Excretion and Excretory Systems

Every organism, from the smallest protist to the largest mammal, must rid itself of the potentially harmful by-products of its own vital activities. This process in living things is called elimination, which may be considered to encompass all of the various mechanisms and processes by which life forms dispose of or throw off waste products, toxic substances, and dead portions of the organism. The nature of the process and of the specialized structures developed for waste disposal vary greatly with the size and complexity of the organism.

Four terms are commonly associated with waste-disposal processes and are often used interchangeably, though not always correctly: excretion, secretion, egestion, and elimination.

Excretion. Excretion is a general term referring to the separation and throwing off of waste materials or toxic substances from the cells and tissues of a plant or animal.

Secretion. The separation, elaboration, and elimination of certain products arising from cellular functions in multicellular organisms is called secretion. Though these substances may be a waste product of the cell producing them, they are frequently useful to other cells of the organism. Examples of secretions are the digestive enzymes produced by intestinal and pancreatic tissue cells of vertebrate animals, the hormones synthesized by specialized glandular cells of plants and animals, and sweat secreted by glandular cells in the skins of some mammals. Secretion implies that the chemical compounds being secreted were synthesized by specialized cells and that they are of functional value to the organism. The disposal of common waste products should not, therefore, be considered to be of a secretory nature.

Egestion. Egestion is the act of excreting unusable or undigested material from a cell, as in the case of single-celled organisms, or from the digestive tract of multi-cellular animals. The elimination of digestive wastes is treated in the article DIGESTION AND DIGESTIVE SYSTEMS.

Elimination. As defined above, elimination broadly defines the mechanisms of waste disposal by living systems at all levels of complexity. The term may be used interchangeably with excretion.

This article discusses the eliminatory processes and mechanisms of various organisms, from the egestion of the simplest single-celled organism to the highly developed excretory process of vertebrates and of human beings. Human excretion, along with the diseases and disorders that disrupt healthy function, is explained in detail.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 421 and 423.

The article is divided into the following sections:

Elimination

BIOLOGICAL SIGNIFICANCE OF ELIMINATION

Waste disposal by unicellular and multicellular organisms is vital to their health and to the continuance of life. Animals must take in (ingest) energy-containing chemical compounds, extract a portion of the energy to power their life processes, and dispose of the unusable material or by-products formed during the energy-extraction process. An analogous series of events occurs in an internal-combustion engine. Fuel, containing energy, is taken into the engine, where it is burned, and a portion of the energy released is used to move the pistons. As in living cells, a portion of the energy-containing material (fuel) not utilized in the engine is exhausted in the form of carbon monoxide, carbon dioxide, and other by-products of combustion. Blockage of the exhaust system in an engine results in loss of efficiency and eventual total breakdown. Similarly, the rate of waste disposal in biological systems can and does provide a means of controlling the metabolic rate. Complete blockage of waste-disposal mechanisms in living systems is as effective in destroying vital functions as the cutting off of food, oxygen, or water from the system. In addition, some substances produced as metabolic by-products are toxic in themselves and must be removed from living cells at a rate equal to that at which they are produced by those cells. Thus, the excretion of waste products from living cells must occur continually in order to ensure the normal progression of vital chemical events.

Importance of elimination in living systems

Waste and poisonous substances produced by the metabolic activities of plant and animal communities must, in a similar manner, be removed or detoxified if community health is to be preserved. Collective wastes of individual organisms constituting a community, if allowed to accumulate to any marked degree, will eventually destroy the lives of all the community members.

The biosphere, composed of all individuals and communities of life forms and their environments on the Earth, is equally sensitive to the effects of waste and poison accumulation. A continual buildup of substances harmful to life forms can only result in the eventual destruction of most or all of the presently existing species of plants and animals. Humans are unique among living things in that their activities result in the production of waste materials (pollutants) that, by virtue of their chemical structure, are poisonous to all living things, including themselves. (For information about waste disposal in the biosphere, see BIOSPHERE and CONSERVATION OF NATURAL RESOURCES.)

TYPES OF WASTE: METABOLIC AND NONMETABOLIC

Waste products may be categorized as metabolic or nonmetabolic. The difference lies in whether the substances in question are produced by the chemical processes of a living cell or are merely passed through the digestive tract of an organism without actually entering into its life processes.

Nonmetabolic wastes. The nonmetabolic wastes are mainly materials that, by virtue of their chemical makeup, are indigestible or unusable by an organism. In addition, nonmetabolic wastes include any substances that are absorbed, ingested, or otherwise taken into a living system in excess of the needs and storage capabilities of the organism. These substances include digestible (metabolizable) as well as indigestible materials, and they may be excreted almost immediately, even though they are often usable as food.

Heat as a waste product

Metabolic wastes. Metabolic wastes may be separated into gases, liquids, solids, and heat. Heat, though usually not classified as a waste product, should be classified as such because it is a by-product of metabolic activity and must be eliminated to avoid harmful elevation of body temperatures in warm-blooded animals.

Gaseous wastes. Oxygen produced during photosynthetic reactions in green plants and certain bacteria may be considered to be a waste product, or at least a by-product, requiring removal. Carbon dioxide is produced by all animals and by green plants in darkness. Nitrogen gas is produced by denitrifying sulfur bacteria (*Thiobacillus*), and ammonia is excreted by decay-causing bacteria and by most invertebrate and vertebrate animals.

Liquid wastes. The sole liquid waste produced as a metabolic by-product by all animals and photosynthetic plants in darkness is water.

Solid wastes. Several important kinds of materials may be classified as solid wastes. Among them are nitrogenous wastes, by-products of protein and amino-acid metabolism by animals; nitrite and nitrate compounds produced by nitrifying bacteria; and sulfur and sulfates resulting from the metabolic activities of sulfur bacteria. Many other substances also enter into solid wastes to be disposed of by organisms. Iron compounds in an insoluble form are secreted by iron bacteria that have used soluble iron compounds. Various resins, fats, waxes, and complex organic chemicals are exuded from certain plants—as in the latex from rubber trees and milkweeds. Organic pigments from the breakdown of biological pigments, such as hemoglobin in vertebrates, become components of solid waste. Inorganic salts, including molecules and ions such as carbonates, bicarbonates, and phosphates resulting from life-sustaining chemical reactions, eventually may become solid waste products.

METHODS OF WASTE DISPOSAL

Disposal of metabolic and nonmetabolic wastes involves both active and passive mechanisms. In general, gaseous wastes are eliminated through passive mechanisms without the direct expenditure of energy on the part of the living system. The solid and liquid waste-disposal mechanisms used by higher animals are active (energy consuming) systems that separate waste materials from vital substances prior to excretion. Methods of disposal may be classified into specific and nonspecific systems.

Specific elimination mechanisms. Three pathways exist in this context: (1) the alimentary canal, (2) the respiratory system, and (3) the kidneys.

Alimentary canal. The alimentary canal is a pathway used almost exclusively for the elimination of solid wastes of an indigestible nature, and the act of elimination by this means is termed egestion. Materials disposed of in this manner have not entered the tissues of the animal but rather are the residues of enzymatic and absorptive activities occurring in the digestive tract. True metabolic wastes are excreted by means of the flow of bile from the liver into the intestine. The destruction of cells in animals produces bile pigments—residues of hemoglobin and other pigments—which may be considered to be the principal metabolic wastes eliminated via the alimentary canal. Waste disposal in this manner requires little energy expenditure other than that employed in the peristaltic contractions of muscle in the walls of the tract that act to push material along the length of the tube (see DIGESTION AND DIGESTIVE SYSTEMS).

Respiratory system. The respiratory pathway is concerned principally with the gaseous waste products of metabolism (carbon dioxide and ammonia), which move to the external environment by diffusing from the cells of origin. In invertebrate and vertebrate members of the animal kingdom, transport is by means of the circulatory system when present or simply by diffusion through the cell membranes of lower animals. A few multicellular aquatic animals lose carbon dioxide to the surrounding water by way of diffusion through the thin vascular membranes of their general body surface. In most higher animals, however, the skin is too hard or thick and nonvascular to function effectively in gas disposal. In these animals, gills and lungs—aggregations of thin, moist, vascular membranes—have evolved. Membranes of the gills of aquatic animals and the lungs of terrestrial forms are provided with large surface areas for the diffusion of waste gases from the circulatory system to the outside environment. Because carbon dioxide is soluble in the body water, it can easily diffuse into the circulatory system, in solution, from the cells of origin. Transport and excretion of carbon dioxide requires little energy as it diffuses along concentration gradients from cells to the circulation and finally to the outside environment.

Carbon dioxide elimination

Because more carbon dioxide (CO_2) is produced by metabolic activity than can be carried in the circulatory system in the form of dissolved carbon dioxide, the major portion of carbon dioxide is transported to the gills and lungs as bicarbonate (HCO_3^-), via two chemical reactions:

$$CO_2 + H_2O \leftrightarrows H_2CO_3 \rightleftarrows H^+ + HCO_3^-.$$

Thus, carbon dioxide reacts with water, producing carbonic acid (H_2CO_3), which in turn dissociates to produce a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-). In the lungs or gills, these reactions occur in the opposite direction, and carbon dioxide diffuses from the body into the outside environment. Certain aquatic animals are capable of eliminating gaseous ammonia—derived from protein breakdown—by way of specialized cells in their gill tissues.

Salt secretion via specialized gill cells occurs in marine vertebrates that constantly absorb salt through thin membranes of their oral, respiratory, and body surfaces (see RESPIRATION AND RESPIRATORY SYSTEMS).

The kidneys. Kidneys have evolved in multicellular animals as a highly sophisticated channel for waste disposal, and they function to regulate the levels of water, salts, and organic materials in the bodies of higher animals. Materials eliminated via the kidney include nitrogenous waste products (ammonia, uric acid, urea, creatine, creatinine, and amino acids), excess quantities of salts and water that may be taken into the body, and various other organic materials produced by life-sustaining chemical reactions. Functionally, the kidney is a microfilter that initially removes dissolved as well as some suspended materials from the circulatory system, along with large quantities of water. These substances are differentially reabsorbed into the blood by various kidney structures during urine formation to a degree that varies considerably throughout the animal kingdom. For example, animals that absorb large quantities of water into their bodies (such as freshwater fishes) excrete copious quantities of water in their urine. The reverse is true of many desert animals, who must conserve water and therefore produce a thick, semisolid urine. The kidney, in its various stages of evolution, functions at the expense of considerable metabolic energy and cannot be considered to be a passive system. (For a specific account of kidney structure and function, see below *Human excretion.*)

Nonspecific mechanisms of waste disposal. A multitude of disposal mechanisms exist throughout the plant and animal kingdoms for the elimination of excess plant and animal material. Among plants, the shedding and dropping of bark, leaves, and twigs might, in a broad sense, be said to represent disposal mechanisms. Certain plants, in addition, secrete or exude resins, sap, and other substances that accumulate in excessive quantities within the plant.

Elimination of particulate wastes

Specialized, mobile, amoeba-like cells exist in the blood and tissues of animals and engulf particulate wastes resulting from the disintegration of dead cells or the intake of foreign particles into the bodies of animals. Waste matter thus stored inside these small cells is removed from contact with the organism or its metabolism and may be considered to be eliminated whether or not the material is ever actually eliminated from the body of the organism during its normal life cycle.

Toxic substances are produced by normal metabolic activities. Though some of these poisons are eliminated in their original chemical form, others, such as some nitrogenous compounds, are altered biochemically to less toxic compounds. In this manner, more of the original waste may be safely stored, or permitted to accumulate without harmful effects to the organism, until it can be eliminated. In addition, toxic chemicals that are inadvertently ingested or produced by bacterial action (infection) are frequently converted to nontoxic forms by enzymatic and antibody (immune) reactions. Such materials can then be eliminated safely with other wastes along normal pathways of excretion.

Heat is eliminated from the bodies of animals by conduction to the external surface of the organism. In animals possessing a circulatory system, heat travels in its fluid from the deeper portions of the body to the surface. At the body surface, heat is lost by physical processes of convection, radiation, conduction, and evaporation of sweat.

COMPARATIVE OVERVIEW OF ELIMINATORY MECHANISMS FROM PROTISTS TO VERTEBRATES

Protista. No specialized elimination mechanisms are present in algae, fungi, protozoans, and slime molds, the main groups of protists. Metabolic wastes (carbon dioxide, water, oxygen, and nitrogenous compounds) diffuse through the cell membranes of these unicellular organisms into the outside environment. Particulate wastes pass from the bodies of certain protozoans to the exterior by way of small openings in the body surface—anal pores and other cell openings. Elimination in protists is carried out passively and therefore requires little or no expenditure of metabolic energy on the part of the organism.

Plants. Plants are not generally considered to possess special mechanisms of elimination. Photosynthetic activities of green plants, in the presence of light, produce oxygen, which diffuses out through openings in the leaves (stomata) or through the cell walls of roots and other plant structures. Excess water passes to the exterior via similar routes and is eliminated by processes of guttation (droplet exudation) and transpiration (evaporation of water from plant surfaces).

Green plants in darkness or plants that do not contain chlorophyll produce carbon dioxide and water as respiratory waste products. Carbon dioxide is secreted in the same manner as oxygen via diffusion through stomata and cell walls. Materials that are exuded by some plants—resins, saps, latexes, etc.—are forced from the interior of the plant by hydrostatic pressures inside the plant and by absorptive forces of plant cells. These forces are passive in nature, and exudation requires no energy expenditure on the part of the plant.

Animals. Diverse mechanisms have evolved that enable the various animal species to inhabit a wide range of environments. In animals whose bodies consist of a single layer of cells, waste disposal is accomplished principally by diffusion from the site of waste production to the outside environment. This method is efficient when the distances over which wastes diffuse are relatively short, when there is a high surface area to volume relationship, and when the rate of waste production is relatively low. In more complex animals, however, waste elimination by diffusion through the body wall to the exterior is less efficient because individual cells are farther removed from the exterior surface of the organism. The presence of specialized mechanisms of elimination in higher animals enables wastes to be rapidly transported to the exterior surface of the body (see below *Vertebrate excretory systems*).

Efficiency of the diffusion mechanism of waste disposal

Sponges. Phylogenetically, the sponges (phylum Porifera) are the simplest of animals. They are multicellular and composed of specialized cells, arranged in a single layer, for the maintenance of life processes. Elimination in these aquatic animals proceeds by diffusion of gaseous wastes into the surrounding water and by the ejection of solid wastes and indigestible material from the digestive cells into the streams of water that constantly flow through the animal.

Cnidarians. The jellyfishes, coral animals, ctenophores, and comb jellies have a rudimentary canallike cavity in their two-layered bodies for the ingestion, digestion, and egestion of food and wastes. Gaseous wastes are eliminated by diffusion, and solid wastes in dissolved or undissolved form pass out through an opening in the body wall that serves the dual purposes of food intake and waste elimination.

Flatworms. Flatworm bodies consist of three layers of cells, and in this aquatic group elimination is similar to that of the less complex animals. Food and solid wastes enter and leave through a common opening in the well-developed digestive tract, which consists of a mouth, pharynx, and gastrovascular cavity.

Nemertine worms. The digestive and excretory system of the aquatic proboscis worms is more efficient than that of lower animals in that a well-defined mouth, intestine, and excretory opening (anus) permit the one-way flow of food and waste through the animal. Egested food and nitrogenous wastes, which are secreted into the intestine, are passed along it to the anus by peristaltic waves of the smooth muscle lining the intestinal walls. The efficiency of waste elimination is increased by the presence of a well-defined circulatory system, which enhances the carriage of wastes to the intestine.

Nematodes. An additional excretory structure has evolved in the roundworms. Excretory canals located on both sides of the intestine facilitate waste disposal by carriage of material to an excretory pore in the body wall.

Other invertebrates. In invertebrates, increasing structural complexity is accompanied by more efficient waste-disposal mechanisms. In the phylum Mollusca (clams, snails, oysters, mollusks, octopuses, and squids), gills add another more efficient channel for waste disposal. A heart increases the rate of flow in the circulatory system and speeds the transport of wastes to the gills. An excretory, kidneylike organ removes metabolic wastes from the circulation and body fluid prior to excretion. All basic mechanisms of excretion are thus present in relatively simple animals. As invertebrates become more specialized and complex, as in the arthropods (insects, crabs, and other joint-legged animals) and annelids (segmented worms), adaptations in excretion methods allow survival in non-aquatic environments.

Vertebrates. Though the wastes produced by vertebrates differ little qualitatively from those of higher invertebrates, increased structural complexity and body size, in combination with environmental adaptations, require more specific waste-disposal mechanisms in order to maintain a constant internal environment. The presence of highly efficient, water-retaining kidneys, for example, permits vertebrates to inhabit arid, hot regions of the earth. It seems proper, within the vertebrate group, to consider elimination schemes as variations of mechanisms common to all higher animals but which enable animals to inhabit widely diversified environments. (F.C.Ke./Ed.)

General features of excretory structures and functions

The physiological process by which an organism disposes of its nitrogenous by-products is called excretion. The mechanisms for that process constitute the excretory systems, particularly such organs of vertebrate animals as elaborate and complicated as the kidney and its associated urinary ducts.

Definitions and distinctions

The meaning of excretion is most easily understood in the context of vertebrate physiology. The animal swallows food (ingestion). In the stomach and intestine some of the food is broken down into soluble products (digestion) that are absorbed into the body (assimilation). In the body these soluble products undergo further chemical change (metabolism); some are used by the body for growth, but most provide energy for the various activities of the body. Metabolism involves the uptake of oxygen and the elimination of carbon dioxide in the lungs (respiration).

Besides carbon dioxide, compounds of nitrogen arise from metabolism and are eliminated, chiefly by the kidney, in the urine (excretion). Food not digested is eliminated through the anus (defecation).

These processes are characteristic of animals in general, but not of plants. A green plant takes in carbon dioxide from the atmosphere and nitrogen (as nitrate) from the soil. It uses the energy of sunlight to build these nutrients into the materials required for growth and in the process gives out oxygen (see PHOTOSYNTHESIS).

In a broad sense animals live on plants, and the by-products of animals are the raw materials on which plants grow. These mutually supporting activities of plants and animals are kept precisely in balance by the activities of bacteria. Bacteria convert the urine and feces of animals (and also the dead bodies of both plants and animals) to carbon dioxide and nitrate. In the living world as a whole, carbon and nitrogen are in continuous circulation, driven by the energy of sunlight (see BIOSPHERE). Over most of the earth, for most of time, no by-products accumulate. Occasionally the cycles get out of balance, as they must have done during the prehistoric period when coal was being formed in the earth as a consequence of the failure of bacteria to decompose all the remains of plants.

PRODUCTS OF EXCRETION

Although every type of organism takes in some materials and eliminates others, excretion in the strict sense is a process found only in animals. For the purposes of this article excretion will be taken to mean the elimination of nitrogenous by-products and the regulation of the composition of the body fluids.

The primary excretory product arising naturally in the animal body is ammonia, derived almost entirely from the proteins of the ingested food. In the process of digestion proteins are broken down into their constituent amino acids. Some of the amino-acid pool is then used by the animal to build up its own proteins, but a great deal is used as a source of energy to drive other vital processes. The first step in the mobilization of amino acids for energy production is deamination, the splitting off of ammonia from the amino-acid molecule. The remainder is oxidized to carbon dioxide and water, with the concomitant production of the energy-rich molecules of adenosine triphosphate (ATP; see METABOLISM).

Since excessive levels of ammonia are highly toxic to most animals, they must be effectively eliminated. This is no problem in small aquatic animals because ammonia rapidly diffuses, is highly soluble in water, and escapes easily into the external medium before its concentration in the body fluids can reach a dangerous level. But in terrestrial animals, and in some of the larger aquatic animals, ammonia is converted into some less harmful compounds (detoxication). In mammals, including humans, it is detoxified to urea, which may be considered as being formed by the condensation of one molecule of carbon dioxide with two molecules of ammonia (though the biochemistry of the process is more complex than that). Urea is highly soluble in water but cannot be excreted in a highly concentrated solution because of the osmotic pressure (see below) it would exert. Because the conservation of water is important for most terrestrial animals, it is not surprising that many of them have evolved more economical methods for disposing of nitrogenous by-products. Birds, reptiles, and terrestrial insects excrete nitrogen in the form of uric acid, which is highly insoluble in water and can be removed from the body as a thick suspension or even as a dry powder.

EXCRETORY MECHANISMS

Osmotic pressure. In order to understand the advantages of the excretion of uric acid over urea it is necessary to know something about the behaviour of molecules in solution. Molecules of a solute (*e.g.*, salt, sugar) in water tend to move by diffusion from a region where they are in high concentration to one where they are in low concentration, and molecules of water tend to move in the opposite direction. If a porous membrane is placed between these regions, the movements of molecules may be variously restricted depending upon their size in relation to the size of the submicroscopic pores in the membrane. The passage of water molecules from pure water through such a membrane into a solution containing molecules that are too large to pass is called osmosis, a process that takes place spontaneously and does not require energy. This process can be reversed by applying hydrostatic pressure to the solution, a process that does require energy. The level of hydrostatic pressure at which there is no net movement of water in either direction across the membrane is called the osmotic pressure of that particular solution; the greater the concentration of dissolved molecules in the solution the greater is its osmotic pressure and the greater the force needed to remove water from it.

The osmotic process

These principles explain why more energy is required to remove water from urine containing urea than from urine containing the same weight of uric acid. The molecule of urea is smaller than that of uric acid, so that with the same weight, there are more molecules of urea to exert osmotic pressure. But an even more important difference is that whereas urea is highly soluble in water, uric acid is not. As water is progressively removed from a solution of urea, the osmotic pressure opposing further removal progressively increases. For the uric acid solution, however, as water is removed, the uric acid comes out of solution, or precipitates, when the solution is at a lower concentration, and, therefore, at a lower osmotic pressure, which does not increase further.

Regulation of water and salt balance. The mechanisms of detoxication that animals use are related to their modes of life. This is true, with greater force, of the mechanisms of homeostasis, the ability of organisms to maintain internal stability. A desert-living mammal constantly faces the problem of water conservation; but a freshwater fish faces the problem of getting rid of the water that enters its body by osmosis through the skin. At the level of the individual cell, whether it is the cell that constitutes a unicellular organism or a cell in the body of a multicellular organism, the problems of homeostasis present themselves in similar ways.

To continue its intracellular processes a cell must maintain an intracellular chemical environment in which the concentrations of various ions (see below) are kept constant in the face of changing concentrations in the medium surrounding the cell. This is the task of the cell membrane. In the higher animals the task is easier since cells in the interior of their bodies are bathed in an internal medium—the blood—whose composition is regulated so as to minimize the effects of changes in the external medium. This regulatory function is undertaken by specialized cells or organs such as the kidney, thereby lessening the regulatory burden of the other cells of the body.

The biological necessity for homeostatic mechanisms is particularly urgent for controlling the inorganic components of cells and body fluids. Inorganic salts can exert even greater osmotic pressure against membranes impermeable to them than urea. This is so because, under the conditions in the body, they are almost completely dissociated into their component ions. For example, a molecule of common salt (sodium chloride) is dissociated into two inorganic ions—a positively charged sodium ion and a negatively charged chloride ion—both of which can exert osmotic pressure.

Aside from their osmotic effects, inorganic ions have profound effects upon metabolic processes, which in general will take place only in the presence of appropriate concentrations of these ions. The most important inorganic ions in organisms are the positively charged hydrogen, sodium, potassium, calcium, and magnesium ions, and the negatively charged chloride, phosphate, and bicarbonate ions. The membranes of cells are not completely impermeable to these ions and are in fact endowed with the ability to transport ions between the inside and outside of the cell, whereby they control the concentrations of ions within the cells; when such transport is in the direction that requires a supply of energy, it is called active transport (see CELLS: *The plasma membrane*).

Active transport of ions

Osmotic regulation is the maintenance of the normal concentration of the body fluids; *i.e.*, the total concentration of all dissolved substances (solutes) that would exert osmotic pressure against a membrane impermeable to them. Osmotic regulation controls the amount of water in the body fluids relative to the amount of osmotically active solutes. Ionic regulation is the maintenance of the concentrations of the various ions in the body fluids relative to one another. There is no consistent distinction between the two processes; organs that participate in one process at the same time participate in the other.

Principal excretory structures. Whereas the kidney is the principal organ subserving both nitrogenous excretion and osmotic and ionic regulation in the mammalian body, these functions are not always performed by a single organ in other animals. As indicated earlier, primitive aquatic animals do not require any special provision for nitrogenous excretion. But by reason of their permeable skins they may have serious problems of osmotic and ionic regulation, especially in fresh water, where cells covering the surface of the body have the ability to actively transport salts into or out of the animal. In some cases these nonkidney regulatory activities are performed by certain specialized cells; *e.g.,* in the gills of fishes (see below). In other cases, specialized cells are assembled into organs of salt uptake or salt elimination; *e.g.,* the salt glands of birds (see below).

This dispersal of the regulatory function may be the primitive condition, for it is only in the more highly evolved terrestrial animals that the regulatory function is restricted to an excretory system proper. This is readily understandable in view of the need of terrestrial animals to conserve water. This evolutionary development toward one system reaches its climax in the birds, reptiles, and terrestrial insects, in which all the processes of elimination that might involve loss of water—defecation, nitrogenous excretion, and ionic regulation—converge upon the same final channel.

For the excretory organs of a wide variety of vertebrate and invertebrate animals, there is evidence that the primary process of urine production is nonselective, in that in those animals all substances dissolved in their body fluids, with the possible exception of proteins, are found in the primary urine. In many animals the primary urine is produced by filtration from the blood. At a later stage, substances in the primary urine that are useful to the body are selectively reabsorbed. In addition, a few substances are known to be actively transported (secreted) into the urine.

The nonselective formation of primary urine serves another aspect of excretion: the elimination of foreign substances. Mechanisms of active transport are highly specific to the substances transported. All dissolved constituents of the body fluids pass freely into the primary urine, and then specific reabsorptive mechanisms gather up the "wanted" substances. In this way a natural economy automatically eliminates "unwanted" substances simply by not providing mechanisms for their reabsorption.

INVERTEBRATE EXCRETORY SYSTEMS

Regulation of body fluids

In their detoxication mechanisms, so far as they have been investigated, the invertebrates in general conform to the principles applying to all animals, namely, that aquatic forms get rid of ammonia by diffusion through the surface of the body; terrestrial forms convert ammonia to uric acid. This implies that in aquatic forms the excretory organ is principally of importance for the composition of their body fluids. Normally, the body fluids of marine invertebrates have the same concentration as seawater; they usually differ, however, in the proportions of ions, with relatively more potassium and less magnesium than seawater. Furthermore, their urine normally has the same concentration as seawater, but correspondingly it contains less potassium and more magnesium. In freshwater invertebrates the urine is commonly, though not invariably, more dilute than the body fluids. By producing dilute urine a freshwater invertebrate conserves the salt content of its body while eliminating the water that enters its body by osmosis through its water-permeable surface.

Some invertebrates, notably echinoderms, cnidarians, and sponges, have no organs to which an excretory function can be confidently ascribed. Since all of these animals are aquatic, it is reasonable to suppose that they excrete nitrogen (as ammonia) by simple diffusion. Their body fluids (where present) are closely similar to seawater in composition, and it may be presumed that regulation operates only at the cellular level.

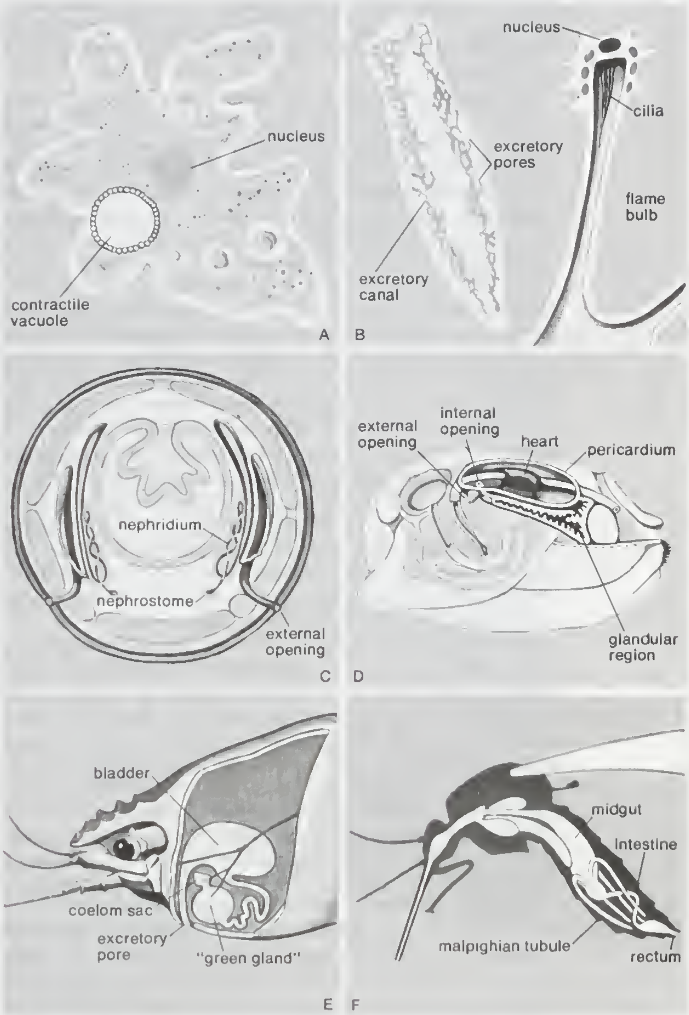

Figure 1. *Invertebrate excretory systems.*
(A) Contractile vacuole of an amoeboid protozoan. (B) Protonephridial system of a flatworm, with enlargement of a single-celled flame bulb that terminates the tubules of excretory canals. (C) Metanephridial system of an earthworm, with paired nephridia in one segment. (D) Renal organ of a clam, cut away to show glandular region. (E) Renal system of a crayfish, exposed through cut-away shell. (F) Excretory system of a mosquito.

The excretory organs of other invertebrates are of diverse evolutionary origin. This is not to say, however, that each invertebrate phylum has evolved its own particular type of excretory organ; rather, there appear to be five main types of invertebrate excretory organ: contractile vacuole, nephridium, renal gland, coxal gland, and malpighian tubule.

The contractile vacuoles of protozoans. Some protozoan animals possess an organelle having the form of an internal sac, or vacuole, which enlarges by the accumulation of a clear fluid and then discharges its contents to the exterior. The cycle of filling and emptying may be repeated as frequently as every half minute. The chief role of the contractile vacuole appears to be in osmotic regulation, not in nitrogen excretion.

Contractile vacuoles occur more frequently and are more active in freshwater species than in closely related marine species. In fresh water, the concentration of dissolved substances in the cell is greater than in the external medium, and the cell takes in water by osmosis. If the contractile vacuole is put out of action, the cell increases in volume. If the concentration of salts in the medium increases—which would have the effect of decreasing the rate of osmosis—the rate of output by the contractile vacuole diminishes. The fluid eliminated by the vacuole is more dilute than the cytoplasm.

The nephridia of annelids, nemertines, flatworms, and rotifers. The word nephridium applies in its strict sense only to the excretory organs of annelids, but it may usefully be extended to include the excretory organs of other phyla having similar characteristics. Annelids are segmented animals that typically contain a pair of nephridia on each segment. Each nephridium has the form of a very fine tubule, often of considerable length; one end usually opens into the body cavity and the other to the exterior. In some annelids, however, the tubule does not open into the body cavity but ends internally in a cluster of cells of a special type known as solenocytes, or flame cells. The possession of solenocytes by some annelids is one of the characteristics that allies them with other nonsegmented phyla that have no true body cavity. They also have a system of tubules opening at the surface and ending internally in flame cells embedded among the other cells of the body. In most cases, there is no regular arrangement of the various parts of the system. Animals belonging to all of these phyla are primarily aquatic, and, in the few cases known, the main excretory product is ammonia. How much of it leaves the body by the nephridia and how much through the body surface is not known.

Few physiological studies have been made on nephridia other than those of the earthworm. Although the earthworm is considered a terrestrial animal, its relationships with its environment are characteristically those of a freshwater animal. The nephridium of the earthworm is longer and more complex than that of marine annelids, four regions being distinguishable. Body fluid enters the nephridium via an internal opening called the nephridiostome. As the fluid passes along the tubule, probably driven by cilia, its composition is modified. In the two lower regions of the tubule the fluid becomes progressively more dilute, presumably as a result of the reabsorption of salts. Finally, a very dilute urine passes into the bladder (an enlarged portion of the tubule) and then to the exterior through the external opening, or nephridiopore. The rate of urine flow for an earthworm may be as much as 60 percent of its body weight in a period of 24 hours.

The common plan of the renal gland

The renal glands of mollusks. The anatomical form of the renal gland varies from one class of mollusks to another, but a common plan is clearly evident. The renal gland is a relatively wide tube opening from a sac (the pericardium) surrounding the heart, at one end, and to the mantle cavity (effectively to the exterior) at the other. There is a single pair of renal glands; in some forms one member of the pair may be reduced or absent. Clams have the simplest arrangement; the region nearest to the pericardium has glandular walls and gives way to a nonglandular, wider tube that extends to the urinary opening.

The vast majority of mollusks are aquatic and excrete nitrogen in the form of ammonia. In octopuses, however, nitrogen is excreted as ammonium chloride, which is quite strongly concentrated in the urine. Terrestrial snails and slugs excrete uric acid but may also excrete ammonia when living in moist surroundings.

In all mollusks so far investigated the primary process in urine production appears to be filtration of the blood. This may take place through the wall of the heart into the pericardium, or from blood vessels that supply the glandular part of the renal gland. The composition of the primary urine may be altered by reabsorption or secretion, or both. In freshwater mollusks salts are reabsorbed in the glandular tube and in the wide tubule, and the final urine is more dilute than the blood. The rate of urine flow is high, up to 45 percent of the body weight per day in the freshwater mussel. In marine mollusks the urine has the same concentration as the blood, but (in the few cases examined) its ionic composition is different.

The coxal glands of aquatic arthropods. Coxal glands are tubular organs, each opening on the basal region (coxa) of a limb. Since arthropods are segmented animals, it is reasonable to suppose that the ancestral arthropod had a pair of such glands in every segment of the body. In modern crustaceans there is, as a rule, only a single pair of glands, and in higher crustaceans these open at the bases of the antennae. Each antennal gland is a compact organ formed of a single tubule folded upon itself. When unraveled the tubule is seen to comprise three or four easily recognizable regions. The tubule arises internally as a small sac, the coelomic sac, which opens into a wider region, the labyrinth, having complex infoldings of its walls. The labyrinth opens either directly into the bladder, as in marine lobsters and crabs, or into a narrow part of the tubule, the canal, which in turn opens into the bladder, as in freshwater crayfishes.

Ion concentration in urine

The coelomic sac, well supplied with blood vessels, gives evidence that the primary process in urine production is filtration of the blood through the wall of the coelomic sac in a manner analogous to filtration in the glomerulus and Bowman's capsule of the vertebrate kidney (see below). In lobsters and marine crabs the urine in all parts of the organ has the same ion concentration as the blood. In freshwater crayfishes the urine has the same concentration as far as the end of the labyrinth; from that point on reabsorption takes place in the canal and the urine leaves the body as a very dilute solution. The addition of the canal to the system demonstrates one way crustaceans have adapted to life in fresh water. But this is not the only way in which the regulatory problem is solved in freshwater crustaceans. In freshwater crabs, for example, there is a great decrease in the water permeability of the surface (principally the gills) so that water enters by osmosis quite slowly. In contrast to the rate of urine flow in a freshwater crayfish (about 5 percent of the body weight per day), that of the freshwater crab is 100 times less (about 0.05 percent). In the crab the urine has the same concentration as the blood, but because the flow is so small the salt loss via the urine is negligible. A few semiterrestrial crabs are known to produce urine more concentrated than the blood.

In all crustaceans for which analyses are available the concentrations of ions in blood and urine differ. At a urine flow of 5 percent of the body weight per day the activities of the antennal glands are certainly capable of effecting changes in the composition of the blood. These activities are somehow coordinated with salt uptake by the cells of the body surface so as to subserve homeostasis. The role of the antennal glands in nitrogenous excretion seems to be unimportant.

The malpighian tubules of insects. Although some terrestrial arthropods (*e.g.,* land crabs, ticks) retain the coxal glands of their aquatic ancestors, others, the insects, have evolved an entirely different type of excretory system. The malpighian tubules, which vary in number from two in some species to more than 100 in others, end blindly in the body cavity (which is a blood space) and open not directly to the exterior but to the alimentary canal at the junction between midgut and hindgut. The primary urine issuing from the malpighian tubules has to pass through the rectum before it leaves the insect's body, and in the rectum its composition is markedly changed. The insect excretory system therefore comprises the malpighian tubules and the rectum acting together.

Primary urine formation in insects

The malpighian tubules are bathed in the insect's blood, but since they are not rigid it is impossible for any hydrostatic pressure to be developed across their walls, such as could bring about filtration. The primary urine is formed by a process of secretion in the following way: Potassium ions are actively transported from the blood into the cavity of the tubule and are necessarily followed by negatively charged ions so as to maintain electroneutrality. In turn, water follows the ions, probably by osmosis, and various other substances—sugars, amino acids, and urate ions—also enter the primary urine by diffusion from the blood.

The primary urine, together with soluble products of digestion and insoluble indigestible matter from the midgut, then passes to the rectum. There (or in some insects at an earlier stage) the urine is acidified and the soluble urate is thereby converted to insoluble uric acid, which comes out of solution. Water is then reabsorbed together with the soluble products of digestion and other useful substances, including the bulk of the ions that entered the primary urine. In insects that live in dry surroundings the rectum has remarkable powers of reabsorption, its contents finally being voided as hard, dry pellets containing solid uric acid.

The activity of the excretory system in insects is under hormonal control. This has been most clearly demonstrated in the case of *Rhodnius,* a bloodsucking bug. Immediately after the ingestion of a blood meal there is a rapid flow of urine whereby most of the water taken in with the blood meal is eliminated. The distension of the body after ingestion is the stimulus that causes certain cells in the central nervous system to release a hormone that acts upon the malpighian tubules to promote a brisk flow of primary urine.

VERTEBRATE EXCRETORY SYSTEMS

The kidney and its associated ducts are the excretory system of the mammal, and, as already noted, most of the nitrogenous waste arising in the mammalian body is excreted as urea. Other nitrogenous compounds regularly present in the urine in smaller amounts are uric acid (or the closely related compound allantoin) and creatinine; both of these arise mainly as by-products of the renewal and repair of tissues.

In birds, reptiles, and amphibians the kidneys are compact organs, as they are in mammals, but in fishes they are narrow bands of tissue running the length of the body (see below under *Evolution of the vertebrate excretory system*). In amphibians, as in mammals, the main excretory product is urea. In birds and reptiles it is uric acid. In most fishes the main excretory product is ammonia.

Mammals. The mammalian kidney (Figure 2) is a compact organ with two distinct regions: cortex and medulla. The functional unit of the kidney is the nephron. Each nephron (Figure 2) is a tubular structure consisting of four regions. It arises in the cortex as a small vesicle about one-fifth of a millimetre (0.008 inch) in diameter, known as Bowman's capsule, into which projects a tuft of capillary blood vessels, the glomerulus. Bowman's capsule is continuous with the proximal convoluted tubule, which also lies in the cortex. Following the proximal convoluted tubule is the loop of Henle, which descends into the medulla and then runs straight up again to the cortex where it continues as the distal convoluted tubule. A collecting tubule, into which several nephrons open, courses through the medulla to open a wide cavity, the pelvis of the kidney. From the pelvis the ureter leads to the bladder, and from the bladder the urethra leads out of the body.

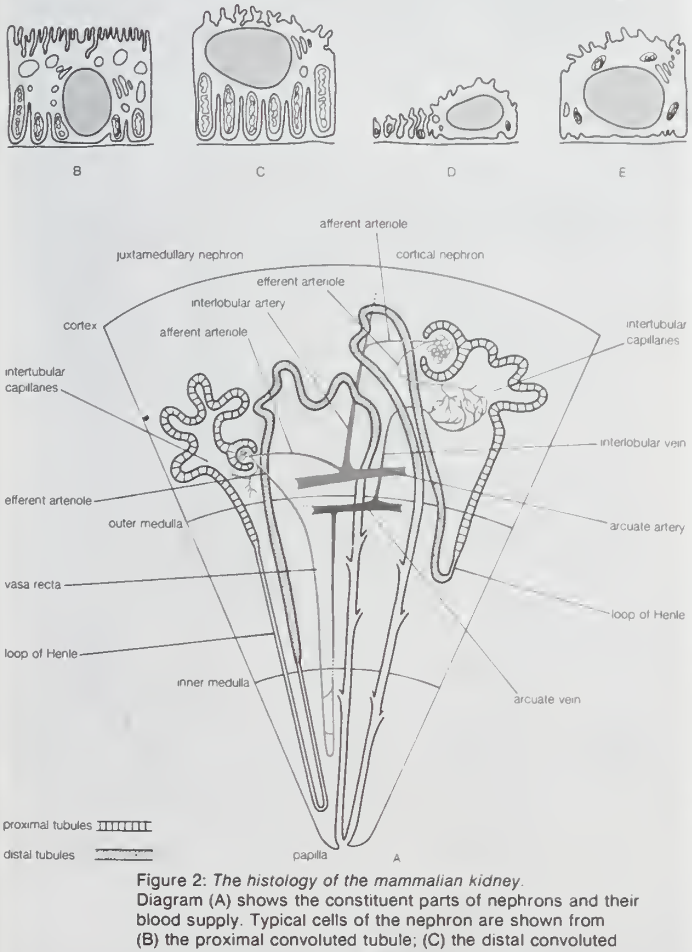

Figure 2: *The histology of the mammalian kidney.*
Diagram (A) shows the constituent parts of nephrons and their blood supply. Typical cells of the nephron are shown from (B) the proximal convoluted tubule; (C) the distal convoluted tubule; (D) the thin limb of the loop of Henle; and (E) the collecting duct. In each case the cell's luminal surface is at the top and the external surface is at the bottom.

Mechanism of urine formation in mammals

The mechanism of urine formation involves three processes: filtration, reabsorption, and secretion. Primary urine is formed by filtration from the blood. From this primary urine certain substances are reabsorbed into the blood and other substances are secreted into the primary urine from the blood. The word secretion is used by renal physiologists to imply transport, other than by filtration, from the blood to urine. Filtration implies that all molecules below a certain size are allowed to pass nonselectively into the primary urine; reabsorption and secretion imply the existence of specific mechanisms for the transport of specific substances.

The membrane covering the glomerulus allows the passage of water and all the constituents of the blood plasma except proteins. The glomerular capillaries are intercalated in the course of an artery, with the consequence that the pressure of the blood in these capillaries is higher than in the capillaries in other parts of the kidney. Opposed to the blood pressure are the pressure of the fluid within Bowman's capsule and the osmotic pressure exerted by the proteins of the blood plasma; but the blood pressure is sufficiently in excess of the sum of these to ensure a rapid flow of fluid, the glomerular filtrate or primary urine, into Bowman's capsule. The glomerular filtrate contains the nitrogenous compounds ultimately to be excreted in the urine. As the glomerular filtrate passes through the proximal tubule, 80 percent of the water, and many substances of value to the body (*e.g.,* glucose), is reabsorbed into the blood capillaries surrounding the tubule. This reabsorptive process is accomplished without any change in the concentration of the tubular fluid, which remains the same as that of the blood plasma.

After traversing the loop of Henle, the remaining 20 percent of the glomerular filtrate passes into the distal tubule, where further reabsorption, notably of salts, takes place. If this is accompanied by a proportionate reabsorption of water, the tubular fluid remains at the same concentration as the blood plasma, but if the reabsorption of water is restricted, as it may be in certain circumstances (see below), the tubular fluid becomes more dilute than the blood plasma. Under normal physiological conditions some 15 percent of the glomerular filtrate is reabsorbed in the distal tubule. Most of the remaining 5 percent is reabsorbed in the collecting tubule. The amount of fluid, at this point called urine, that reaches the pelvis of the kidney is only 1 percent of the volume originally filtered at the glomerulus; but it contains nearly all the nitrogenous waste of the filtrate in concentrated solution. A few substances are also secreted from the blood through the walls of the tubule into the tubular fluid.

The action of the loop of Henle is more difficult to describe, and a full account is given below under *The human excretory system.*

Characteristics of the uric acid of birds and reptiles

Birds and reptiles. The main excretory product of birds and reptiles is uric acid. Since their glomeruli are relatively small, so also is their daily volume of urine. Not highly concentrated by mammalian standards—although it may be turbid with crystals of uric acid—the urine of birds and reptiles is conducted not to a urinary bladder but to the terminal portion of the alimentary canal, the cloaca; from the cloaca it is voided with the feces. Like mammals, and unlike the lower vertebrates, birds and reptiles have skins impermeable to water and thus are well adapted to terrestrial life. The relative inability of the kidney to produce concentrated urine is compensated for in birds that possess salt glands, which remove excess salt from their bodies. These organs are modified tear glands that discharge a concentrated solution of sodium chloride through the nostrils. Salt glands enable marine birds to drink seawater with no ill effects.

Amphibians. Direct evidence for the occurrence of filtration at the glomerulus was first provided by experiments on the amphibian kidney. Although amphibians are formally given the status of terrestrial animals, they are poorly adapted to life on land. They excrete nitrogen in the form of urea and cannot produce urine more concentrated than the blood. Their skins are permeable to water. On land amphibians are liable to lose water very rapidly by evaporation. In fresh water they suffer entry of water by osmosis, which is counteracted by the excretion of a large volume of dilute urine. The urine is stored in a large bladder before being voided, providing a reserve of water the animal can use when it comes on land.

When an amphibian leaves the water, a number of physiological adjustments are made that have the effect of conserving water. The rate of glomerular filtration is reduced by restriction of the blood supply, and this together with an increased release of antidiuretic hormone results in the production of a small volume of urine of the same concentration as the blood. Antidiuretic hormone (ADH, also known as vasopressin, which increases the permeability of the distal and collecting tubules to water) also increases the permeability of the bladder to water and allows the stored urine to be reabsorbed into the body.

Fishes. The homeostasis problem is the same for freshwater fishes as for other freshwater animals. Water enters the body by osmosis and salts leach out. To compensate, the kidney (which has large glomeruli) produces a relatively large amount of dilute urine (about 20 percent of the body weight per day). This serves to remove the water but by itself is insufficient to prevent gradual loss of salts. Extremely diluted salts are taken up from the fresh water and transported directly into the blood by certain specialized cells in the gills. Nitrogenous excretion is no problem: some ammonia is carried away in the large volume of dilute urine, but most of it simply escapes to the external medium by diffusing through the gills.

Excretion in marine fishes

By contrast, the homeostasis problem of marine fishes is unlike that of most marine animals. The salt content of the blood of marine fishes is less than half that of seawater (see below *Evolution of the vertebrate excretory system*); consequently, marine fishes tend to lose water and gain salt. This, it would seem, could be compensated most easily by the excretion of urine more concentrated than the blood, but the kidneys of fishes are not able to do this. In marine bony fishes the kidney has small glomeruli and produces only a small amount (about 4 percent of the body weight per day) of urine, which is of the same concentration as the blood. The fish replaces its lost water by continually swallowing seawater, and the special cells of the gills, working in reverse, reject salt to the external medium. Nitrogen is excreted mostly as ammonia but also as another detoxication product, trimethylamine oxide.

In sharks and rays ammonia is converted to urea, and urea plays an important role in homeostasis. Urea is retained in the blood to such an extent that the blood is slightly more concentrated than seawater. Thus loss of water by osmosis is prevented and these fish have no need to swallow seawater. Any excess of salt in their bodies is removed via the rectal gland, functionally analogous to the salt gland of birds.

Osmotic and ionic regulation in fishes is under hormonal control. This has been studied particularly in fishes such as eels and salmon, which are able to move between fresh water and seawater.

Evolution of the vertebrate excretory system. Studies of the embryonic development of primitive vertebrates, such as the dogfish shark, clearly show that the excretory system arises from a series of tubules, one pair in every segment of the body between the heart and the tail. This continuous series of tubules constitutes the archinephros, the name implying that the kidney of the ancestral vertebrate had some such form as this. Each tubule opens internally to the body cavity and may, in the remote past, have opened separately to the exterior; but in all living vertebrates the tubules open on each side into a longitudinal duct, the archinephric duct. At the posterior end of the body cavity the two archinephric ducts unite before opening to the exterior. Later in development, Bowman's capsule arises as a diverticulum of each tubule, subsequently becoming indented by the glomerulus. Eventually, the tubules usually lose their internal openings to the body cavity. The most anterior tubules of the archinephros (pronephros) usually degenerate in the adult.

Relationship between excretory and reproductive systems

These ducts and tubules also subserve the reproductive function, and for this reason they are also called the urogenital system. The extent to which the ducts and tubules are shared is greater in the male than in the female. In the male the spermatic tubules of the testis connect with the kidney tubules in the middle region of the archinephros (mesonephros), and in some vertebrates (*e.g.,* the frog) where there is no development of the posterior region (metanephros), the tubules of the mesonephros serve to convey both urine and sperm. In the reptiles, birds, and mammals there is greater separation of function, the mesonephros being exclusively genital and the metanephros being exclusively urinary (see Figure 3).

In the female, even in the lower vertebrates, the two systems are confluent only at the posterior end. It has been held that the oviduct is a derivative of the archinephric duct, but the evidence for this is not compelling.

In primitive marine animals the blood is almost identical with seawater in composition; in typical freshwater animals the concentration of the blood is about half that of seawater. Many originally marine animals have evolved the ability to live in fresh water; relatively few animals, after having thus evolved, have returned to the sea, and in none of them has the blood returned to its original "seawa-

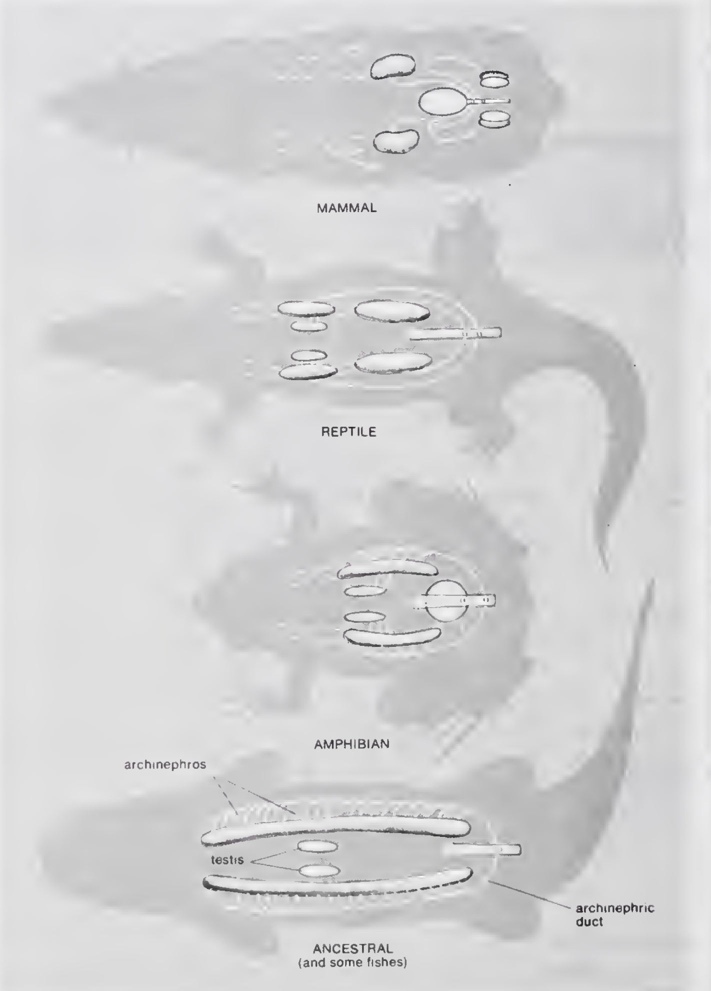

Figure 3: *Evolution of the urogenital system in male vertebrates.* The ancestral archinephric condition has evolved in different patterns for the amphibians, reptiles, and mammals (birds have a pattern similar to reptiles). The broken lines indicate the change in ancestral plan in each of the major vertebrate classes.

ter" concentration. The earliest fossil vertebrates are found in marine deposits, but the fossil record shows clearly that the early evolution of fishes took place in fresh water. It is assumed that the blood of early freshwater fishes, like that of other freshwater animals, was osmotically equivalent to half-strength seawater. The sharks and rays returned to the sea during the Carboniferous Period, and no doubt at that time they evolved the device of urea retention. The bony fishes returned to the sea later, in the Mesozoic Era, and solved their problem by swallowing seawater and rejecting excess salt at the gills. (J.A.R./Ed.)

The human excretory system

In many respects the human excretory, or urinary, system resembles those of other mammalian species, but it has its own unique structural and functional characteristics. The terms excretory and urinary emphasize the eliminatory function of the system. The kidneys, however, both secrete and actively retain within the body certain substances that are as critical to survival as those that are eliminated.

The system contains two kidneys, which control the electrolyte composition of the blood and eliminate dissolved waste products and excess amounts of other substances from the blood; the latter substances are excreted in the urine, which passes from the kidneys to the bladder by way of two thin muscular tubes called the ureters. The bladder is a sac that holds the urine until it is eliminated through the urethra (Figure 4).

THE KIDNEYS

General description and location. The kidneys are bean-shaped, reddish brown paired organs, concave on one long side and convex on the opposite. They are normally located high in the abdominal cavity and against its back wall, lying on either side of the vertebral column between the levels of the 12th thoracic and third lumbar vertebrae, and outside the peritoneum, the membrane that lines the abdomen.

Figure 4: Human renal excretory system.

The long axes of the kidneys are aligned with that of the body, but the upper end of each kidney (pole) is tilted slightly inward toward the backbone (vertebral column). Situated in the middle of the medial concave border is a deep vertical cleft, the hilus, which leads to a cavity within the kidney known as the renal (kidney) sinus. The hilus is the point of entry and exit of the renal arteries and veins, lymphatic vessels, nerves, and the enlarged upper extension of the ureters.

Renal vessels and nerves. The renal arteries arise, one on each side, from the abdominal aorta at a point opposite the upper border of the second lumbar vertebra (*i.e.*, a little above the small of the back). Close to the renal hilus each artery gives off small branches to the adrenal gland and ureter and then branches into anterior and posterior divisions. The large veins carrying blood from the kidneys usually lie in front of the corresponding arteries and join the inferior vena cava almost at right angles. The left vein is longer than the right vein because the inferior vena cava lies closer to the right kidney.

The kidneys are supplied with sympathetic and parasympathetic nerves of the autonomic nervous system, and the renal nerves contain both afferent and efferent fibres (afferent fibres carry nerve impulses to the central nervous system; efferent fibres, from it).

Types of kidney tissue

Internal configuration. A cross section of a kidney reveals the renal sinus and two layers of kidney tissue distinguishable by their texture and colour. The innermost tissue, called the renal medulla, forms comparatively dark cones, called renal pyramids, with bases outward and apexes projecting, either singly or in groups, into the renal sinus. Each projection of one or more pyramid apexes into the sinus is known as a renal papilla. The bases of these pyramids are irregular, with slender striations extending toward the external kidney surface. The paler, more granular tissue external to the medulla is the cortex. It arches over the bases of the pyramids and fills gaps between the pyramids. Each group of pyramids that projects into a papilla, together with the portion of cortex that arches over the group, is called a renal lobe.

The renal sinus includes the renal pelvis, a funnel-shaped expansion of the upper end of the ureter, and, reaching into the kidney substances from the wide end of the funnel, two or three extensions of the cavity called the major calyxes. The major calyxes are divided in turn into four to 12 smaller cuplike cavities, the minor calyxes, into which the renal papillae project. The renal pelvis serves as the initial reservoir for urine, which flows into the sinus through the urinary collecting tubules, small tubes that open into the sinus at the papillae.

The nephrons

Minute structure. The structural units of the kidneys that actually produce urine are the nephrons, of which there are approximately 1,000,000 in each kidney. Each nephron is a long tubule (or extremely fine tube) that is closed, expanded, and folded into a double-walled cuplike structure at one end. This structure, called the renal corpuscular capsule, or Bowman's capsule, encloses a cluster of capillaries (microscopic blood vessels) called the glomerulus. The capsule and glomerulus together constitute a renal corpuscle, also called a malpighian body. Blood flows into and away from the glomerulus through small arteries (arterioles) that enter and exit the glomerulus through the open end of the capsule. This opening is called the vascular pole of the corpuscle.

The tubules of the nephrons are 30–55 millimetres (1.2–2.2 inches) long. The corpuscle and the initial portion of each tubule, called the proximal convoluted tubule, lie in the renal cortex. The tubule descends into a renal pyramid, makes a U-shaped turn, and returns to the cortex at a point near its point of entry into the medulla. This section of the tubule, consisting of the two parallel lengths and the bend between them, is called the loop of Henle or the nephronic loop. After its reentrance into the cortex, the tubule returns to the vascular pole (the opening in the cuplike structure of the capsule) of its own nephron. The final portion of the tubule, the distal convoluted tubule, leads from the vascular pole of the corpuscle to a collecting tubule, by way of a short junctional tubule. Several of the collecting tubules join together to form a somewhat wider tubule, which carries the urine to a renal papilla and the renal pelvis.

Although all nephrons in the kidney have the same general disposition, there are regional differences, particularly in the length of the loops of Henle. Glomeruli that lie deep in the renal cortex near the medulla (juxtamedullary glomeruli) possess long loops of Henle that pass deeply into the medulla, whereas more superficial cortical glomeruli have much shorter loops. Among different animal species the length of the loops varies considerably and affects the ability of the species to concentrate urine above the osmotic concentration of plasma.

The successive sections of the nephron tubule vary in shape and calibre, and these differences, together with differences in the cells that line the sections, are associated with specific functions in the production of urine.

Intrarenal network of blood vessels. The intrarenal network of blood vessels forms part of the blood-processing apparatus of the kidneys.

Arteries and arterioles. The anterior and posterior divisions of each renal artery, mentioned earlier, divide into lobar arteries, each of which enters the kidney substance through or near a renal papilla. Each lobar artery gives off two or three branches, called interlobar arteries, which run outward between adjacent renal pyramids. When these reach the boundary between the cortex and the medulla they split almost at right angles into branches called arcuate arteries that curve along between the cortex and the medulla parallel to the surface of the kidney. Many arteries, called interlobular arteries, branch off from the arcuate arteries and radiate out through the cortex to end in networks of capillaries in the region just inside the capsule. En route they give off short branches called the afferent arterioles, which carry blood to the glomeruli where they divide into four to eight loops of capillaries in each glomerulus (Figure 5).

Near and before the point where the afferent arteriole enters the glomerulus, its lining layer becomes enlarged and contains secretory granules. This composite structure is called the juxtaglomerular apparatus (JGA) and is believed to be involved in the secretion of renin (see below *The role of hormones in renal function*). They are then reconstituted near the point of entry of the afferent arteriole to become the efferent arterioles carrying blood away from the glomeruli. The afferent arterioles are almost twice as thick as the efferent arterioles because they have thicker muscular coats, but the sizes of their channels are almost the same.

Throughout most of the cortex the efferent arterioles redivide into a second set of capillaries, which supply blood to the proximal and distal renal tubules.

Arterioles in the juxtamedullary zone

The efferent glomerular arterioles of juxtaglomerular glomeruli divide into vessels that supply the contiguous tubules and vessels that enter the bases of the renal pyramids. Known as vasa recta, these vessels run toward the apexes of the pyramids in close contact with the loops of Henle. Like the tubules they make hairpin bends, retrace their path, and empty into arcuate veins that parallel the arcuate arteries.

Normally the blood circulating in the cortex is more abundant than that in the medulla (amounting to over 90 percent of the total), but in certain conditions, such as those associated with severe trauma or blood loss, cortical vessels may become constricted while the juxtamedullary circulation is preserved. Because the cortical glomeruli and tubules are deprived of blood, the flow of urine is diminished, and in extreme cases may cease.

Veins and venules. The renal venules (small veins) and veins accompany the arterioles and arteries and are referred to by similar names. The venules that lie just beneath the renal capsule, called stellate venules because of their radial arrangement, drain into interlobular venules. In turn these combine to form the tributaries of the arcuate, interlobar, and lobar veins. Blood from the renal pyramids passes into vessels, called venae rectae, which join the arcuate veins. In the renal sinus the lobar veins unite to form veins corresponding to the main divisions of the renal arteries, and they normally fuse to constitute a single renal vein in or near the renal hilus.

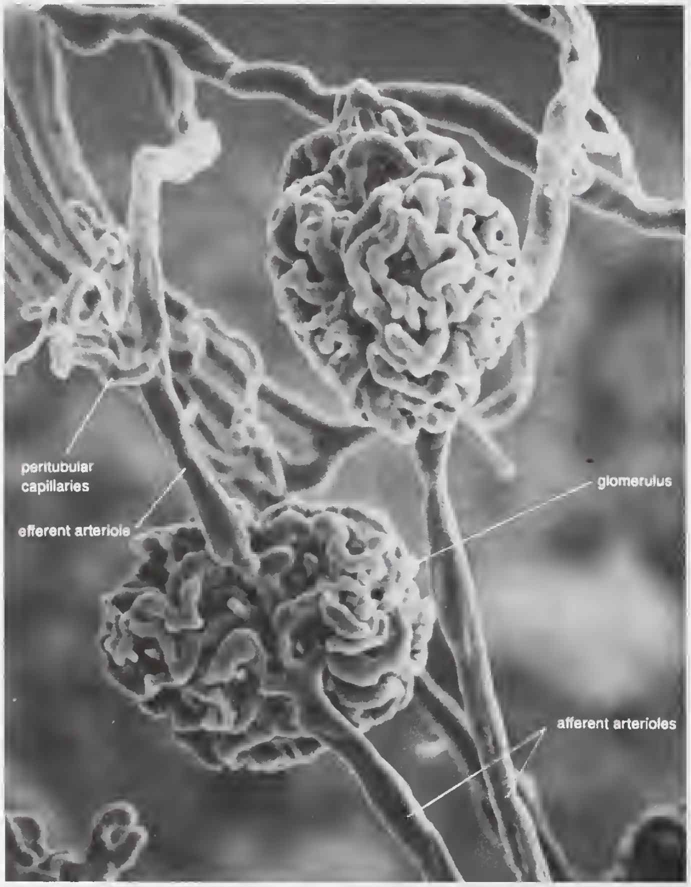

Figure 5: A cast of the intrarenal vascular network. The afferent arteriole enters the glomerulus, where it divides into capillary loops. These are rejoined to become the efferent arteriole, which leaves the glomerulus and branches into numerous peritubular capillaries.

By courtesy of Andrew P. Evan and Vincent H. Gattone II

Lymphatic network. Lymphatic capillaries form a network just inside the renal capsule and another, deeper network between and around the renal blood vessels. Few lymphatic capillaries appear in the actual renal substance, and those present are evidently associated with the connective tissue framework, while the glomeruli contain no lymphatics. The lymphatic networks inside the capsule and around the renal blood vessels drain into lymphatic channels accompanying the interlobular and arcuate blood vessels. The main lymph channels run alongside the main renal arteries and veins to end in lymph nodes beside the aorta and near the sites of origin of the renal arteries.

THE URETERS

General characteristics. The ureters are narrow, thick-walled ducts, about 25–30 centimetres (9.8–11.8 inches) in length and from four to five millimetres (0.16 to 0.2 inch) in diameter, that transport the urine from the kidneys to the urinary bladder. Throughout their course they lie behind the peritoneum, the lining of the abdomen and pelvis, and are attached to it by connective tissue.

In both sexes the ureters enter the bladder wall about five centimetres apart, although this distance is increased when the bladder is distended with urine. The ureters run obliquely through the muscular wall of the bladder for nearly two centimetres before opening into the bladder cavity through narrow apertures. This oblique course provides a kind of valvular mechanism; when the bladder becomes distended it presses against the part of each ureter that is in the muscular wall of the bladder, and this helps to prevent the flow of urine back into the ureters from the bladder.

Structure of the ureteric wall. The wall of the ureter has three layers, the adventitia, or outer layer; the intermediate, muscular layer; and the lining, made up of mucous membrane. The adventitia consists of fibroelastic connective tissue that merges with the connective tissue behind the peritoneum. The muscular coat is composed of smooth (involuntary) muscle fibres and, in the upper two-thirds of the ureter, has two layers—an inner layer of fibres arranged longitudinally and an outer layer disposed circularly. In the lower third of the ureter an additional longitudinal layer appears on the outside of the vessel. As each ureter extends into the bladder wall its circular fibres disappear, but its longitudinal fibres extend almost as far as the mucous membrane lining the bladder.

The mucous membrane lining increases in thickness from the renal pelvis downward. Thus, in the pelvis and the calyxes of the kidney the lining is two to three cells deep; in the ureter, four to five cells thick; and in the bladder, six to eight cells. The mucous membrane of the ureters is arranged in longitudinal folds, permitting considerable dilation of the channel. There are no true glands in the mucous membrane of the ureter or of the renal pelvis. The chief propelling force for the passage of urine from the kidney to the bladder is produced by peristaltic (wavelike) movements in the ureter muscles.

Peristalsis in the ureters

THE URINARY BLADDER

General description. The urinary bladder is a hollow muscular organ forming the main urinary reservoir. It rests on the anterior part of the pelvic floor (see below), behind the symphysis pubis and below the peritoneum. (The symphysis pubis is the joint in the hip bones in the front midline of the body.) The shape and size of the bladder vary according to the amount of urine that the organ contains. When empty it is tetrahedral and lies within the pelvis; when distended it becomes ovoid and expands into the lower abdomen. It has a body, with a fundus, or base; a neck; an apex; and a superior (upper) and two inferolateral (below and to the side) surfaces, although these features are not clearly evident except when the bladder is empty or only slightly distended.

The neck of the bladder is the area immediately surrounding the urethral opening; it is the lowest and most fixed part of the organ. In the male it is firmly attached to the base of the prostate, a gland that encircles the urethra.

The superior surface of the bladder is triangular and is covered with peritoneum. The bladder is supported on the levator ani muscles, which constitute the major part of the floor of the pelvic cavity. The bladder is covered, and to a certain extent supported, by the visceral layer of the pelvic fascia. This fascial layer is a sheet of connective tissue that sheaths the organs, blood vessels, and nerves of the pelvic cavity. The fascia forms, in front and to the side, ligaments, called pubovesical ligaments, that act as a kind of hammock under the inferolateral surfaces and neck of the bladder.

Blood and nerve supplies. The blood supply of the bladder is derived from the superior, middle, and inferior vesical (bladder) arteries. The superior vesical artery supplies the dome of the bladder, and one of its branches (in males) gives off the artery to the ductus deferens, a part of the passageway for sperm. The middle vesical artery supplies the base of the bladder. The inferior vesical artery supplies the inferolateral surfaces of the bladder and assists in supplying the base of the bladder, the lower end of the ureter, and other adjacent structures.

The nerves to the bladder

The nerves to the urinary bladder belong to the sympathetic and the parasympathetic divisions of the autonomic nervous system. The sympathetic nerve fibres come from the hypogastric plexus of nerves that lie in front of the fifth lumbar vertebra. Sympathetic nerves carry to the central nervous system the sensations associated with distention of the bladder and are believed to be involved in relaxation of the muscular layer of the vesical wall and with contraction of sphincter mechanism that closes the opening into the urethra. The parasympathetic nerves travel to the bladder with pelvic splanchnic nerves from the second through fifth sacral spinal segment. Parasympathetic nerves are concerned with contraction of the muscular walls of the bladder and with relaxation of its sphincter. Consequently they are actively involved in urination and are sometimes referred to as the emptying, or detrusor, nerves.

Structure of the bladder wall. The bladder wall has a serous coat over its upper surface. This covering is a continuation of the peritoneum that lines the abdominal cavity; it is called serous because it exudes a slight amount of lubricating fluid called serum. The other layers of the bladder wall are the fascial, muscular, submucous, and mucous coats.

The fascial coat is a layer of connective tissue, such as that which covers muscles. The muscular coat consists of coarse fascicles, or bundles, of smooth (involuntary) muscle fibres arranged in three strata, with fibres of the outer and inner layers running lengthwise, and with fibres of the intermediate layer running circularly; there is considerable intermingling of fibres between the layers. The smooth muscle coat constitutes the powerful detrusor muscle, which causes the bladder to empty.

The circular or intermediate muscular stratum of the vesical wall is thicker than the other layers. Its fibres, although running in a generally circular direction, do interlace. The internal muscular stratum is an indefinite layer of fibres that are mostly directed longitudinally. The submucous coat consists of loose connective tissue containing many elastic fibres. It is absent in the trigone, a triangular area whose angles are at the two openings for the ureters and the single internal urethral opening. Slim bands of muscle run between each ureteric opening and the internal urethral orifice; these are thought to maintain the oblique direction of the ureters during contraction of the bladder. Another bundle of muscle fibres connects the two ureteric openings and produces a slightly downwardly curved fold of mucous membrane between the openings.

The mucous coat of the bladder

The mucous coat, the innermost lining of the bladder, is an elastic layer impervious to urine. Over the trigone it firmly adheres to the muscular coat and is always smooth and pink whether the bladder is contracted or distended. Elsewhere, if the bladder is contracted, the mucous coat has multiple folds and a red, velvety appearance. When the bladder is distended, the folds are obliterated, but the difference in colour between the paler trigonal area and the other areas of the mucous membrane persists. The mucous membrane lining the bladder is continuous with that lining the ureters and the urethra.

THE URETHRA

The male urethra

General description. The urethra is the channel that conveys the urine from the bladder to the exterior. In the male it is about 20 centimetres long and carries not only the urine but also the semen and the secretions of the prostate, bulbourethral, and urethral glands. During urination and ejaculation it opens up, and its diameter then varies from 0.5 to 0.8 centimetre along its length, but at other times its walls touch and its lining is raised into longitudinal folds. The male urethra has three distinguishable parts, the prostatic, the membranous, and the spongy, each part being named from the structures through which it passes rather than from any inherent characteristics.

The prostatic section of the male urethra commences at the internal urethral orifice and descends almost vertically through the prostate, from the base of the gland to the apex, describing a slight curve with its concavity forward. It is about 2.5 to three centimetres long and is spindle-shaped; its middle portion is the widest and most dilatable part of the urethra. The membranous part of the male urethra is in the area between the two layers of a membrane called the urogenital diaphragm. The urethra is narrower in this area than at any other point except at its external opening and is encircled by a muscle, the sphincter urethrae. The two small bulbourethral glands are on either side of it. The membranous urethra is not firmly attached to the layers of the urogenital diaphragm. The spongy part of the male urethra is that part of the urethra that traverses the penis. It passes through the corpus spongiosum of the penis. The ducts of the bulbourethral glands enter the spongy urethra about 2.5 centimetres below the lower layer of the urogenital membrane; except near its outer end, many mucous glands also open into it.

The female urethra

The female urethra is much shorter (three to 4.5 centimetres) and more distensible than the corresponding channel in males and carries only urine and the secretions of mucous glands. It begins at the internal opening of the urethra into the bladder and curves gently downward and forward through the urogenital diaphragm, where it is surrounded, as in the male, by the sphincter urethrae. It lies behind and below the symphysis pubis. Except for its uppermost part, the urethra is embedded in the anterior wall of the vagina. The external urethral orifice is immediately in front of the vaginal opening, about 2.5 centimetres behind the clitoris, and between the labia minora, the inner folds at the outer opening of the vagina.

Structure of urethral wall. The urethra of the male is a tube of mucous membrane supported on a submucous layer and an incomplete muscular coat. The membrane forms longitudinal folds when the tube is empty; these folds are more prominent in the membranous and spongy parts. There are many glands in the mucous membrane, and they are more common in the posterior wall of the spongy part. The submucous layer is composed of fibroelastic connective tissue containing numerous small blood vessels, including more venules than arterioles. The thin muscular coat consists of smooth (involuntary) and striated (voluntary) muscle fibres. The smooth muscular layer, longitudinally disposed, is continuous above with the detrusor muscle of the bladder and extends distally as far as the membranous urethra, where it is replaced and partly surrounded by striated muscle of the external sphincter. The somatic nerves to the external sphincter are the efferent and afferent components of the pudendal nerve, arising from the second, third, and fourth sacral segments of the spinal cord.

The female urethra has mucous, submucous, and muscular coats. As in the male, the lining of the empty channel is raised into longitudinal folds. It also shows mucous glands, mentioned in the preceding paragraphs as existing in the male urethra. The submucous coat resembles that in the male, except that the venules are even more prominent. In both sexes, but especially in females, this layer appears to be a variety of erectile tissue. The muscular coat extends along the entire length of the female urethra and is continuous above with the musculature of the bladder. It consists of inner longitudinal and outer circular layers, and fibres from the latter intermix with those in the anterior wall of the vagina, in which the urethra is embedded.

Human excretion

GENERAL FUNCTION OF THE KIDNEY

The kidney has evolved so as to enable humans to exist on land where water and salts must be conserved, wastes excreted in concentrated form, and the blood and the tissue fluids strictly regulated as to volume, chemical composition, and osmotic pressure. Under the drive of arterial pressure, water and salts are filtered from the blood through the capillaries of the glomerulus into the lumen, or passageway, of the nephron, and then most of the water and the substances that are essential to the body are reabsorbed into the blood. The remaining filtrate is drained off as urine. The kidneys, thus, help maintain a constant internal environment despite a wide range of changes in the external environment.

Regulatory functions. The kidneys regulate three essential and interrelated properties of the tissues—water content, acid-base balance, and osmotic pressure—in such a way as to maintain electrolyte and water equilibrium; in other words, the kidneys are able to maintain a balance between quantities of water and the quantities of such chemicals as calcium, potassium, sodium, phosphorus, and sulfate in solution. Unless the concentrations of mineral ions such as sodium, crystalloids such as glucose, and wastes such as urea are maintained within narrow normal limits, bodily malfunction rapidly develops leading to sickness or death.

The removal of both kidneys causes urinary constituents to accumulate in the blood (uremia), resulting in death in 14–21 days if untreated. (The term uremia does not mean that urea is itself a toxic compound responsible for illness and death.) Whenever the blood contains an abnormal constituent in solution or an excess of normal constituents including water and salts, the kidneys excrete these until normal composition is restored. The kidneys are the only means for eliminating the wastes that are the end products of protein metabolism. They do not themselves modify the waste products that they excrete, but transfer them to the urine in the form in which they are produced in other parts of the body. The only exception to this is their ability to manufacture ammonia. The kidneys also eliminate drugs and toxic agents. Thus, the kidneys eliminate the unwanted end products of metabolism, such as urea, while limiting the loss of valuable substances, such as glucose. In maintaining the acid-base equilibrium, the kidneys remove the excess of hydrogen ions produced from the normally acid-forming diet and manufacture ammonia to remove these ions in the urine as ammonium salts.

Volumes of blood, water, and urine processed by kidneys

To carry on its functions the kidney is endowed with a relatively huge blood supply. The blood processed in the kidneys amounts to some 1,200 millilitres a minute, or 1,800 litres (about 475 gallons) a day, which is 400 times the total blood volume and roughly one-fourth the volume pumped each day by the heart. Every 24 hours 170 litres (45 gallons) of water are filtered from the bloodstream into the renal tubules; and by far the greater part of this—some 168.5 litres of water together with salts dissolved in it—is reabsorbed by the cells lining the tubules and returned to the blood. The total glomerular filtrate in 24 hours is no less than 50–60 times the volume of blood plasma (the blood minus its cells) in the entire body. In a 24-hour period, an average man eliminates only 1.5 litres of water, containing the waste products of metabolism, but the actual volume varies with fluid intake and occupational and environmental factors. With vigorous sweating it may fall to 500 millilitres (about a pint) a day; with a large water intake it may rise to three litres, or six times as much. The kidney can vary its reabsorption of water to compensate for changes in plasma volume resulting from dehydration or overhydration.

Nonexcretory functions. The kidneys also perform certain nonexcretory functions. They secrete substances that enter the blood. These are of three kinds: renin, which is concerned indirectly with the control of electrolyte balance and blood pressure; erythropoietin, which is important for the formation of hemoglobin and red blood cells, especially in response to anemia or deficiency of oxygen reaching the body tissues; and 1,25-dihydroxycholecalciferol, which is the metabolically active form of vitamin D. Finally, although the kidneys are subject to both nervous and humoral (hormonal) control, they do possess a considerable degree of autonomy; *i.e.,* function continues in an organ isolated from the nervous system but kept alive with circulating fluid. Indeed, if this were not so kidney transplantation would be impossible.

RENAL BLOOD CIRCULATION

Intrarenal blood pressures. The renal arteries are short and spring directly from the abdominal aorta, so that arterial blood is delivered to the kidneys at maximum available pressure. As in other vascular beds, renal perfusion is determined by the renal arterial blood pressure and vascular resistance to blood flow. Evidence indicates that in the kidneys the greater part of the total resistance occurs in the glomerular arterioles. The muscular coats of the arterioles are well supplied with sympathetic vasoconstrictor fibres (nerve fibres that induce narrowing of the blood vessels), and there is also a small parasympathetic supply from the vagus and splanchnic nerves that induces dilation of the vessels. Sympathetic stimulation causes vasoconstriction and reduces urinary output. The vessel walls are also sensitive to circulating epinephrine and norepinephrine hormones, small amounts of which constrict the efferent arterioles and large amounts of which constrict all the vessels; and to angiotensin, which is a constrictor agent closely related to renin. Prostaglandins may also have a role.

Factors that affect renal flow. The kidney is able to regulate its internal circulation regardless of the systemic blood pressure, provided that the latter is not extremely high or extremely low. The forces that are involved in maintaining a circulation of the blood in the kidneys must remain constant if the monitoring of the water and electrolyte composition of the blood is to proceed undisturbed. This regulation is preserved even in the kidney cut off from the nervous system and, to a lesser extent, in an organ removed from the body and kept viable by having salt solutions of physiologically suitable concentrations circulated through it; it is commonly referred to as autoregulation.

The exact mechanism by which the kidney regulates its own circulation is not known, but various theories have been proposed: (1) Smooth muscle cells in the arterioles may have an intrinsic basal tone (normal degree of contraction) when not affected by nervous or humoral (hormonal) stimuli. The tone responds to alterations in perfusion pressure in such a way that when the pressure falls the degree of contraction is reduced, preglomerular resistance is lowered, and blood flow is preserved. Conversely, when perfusion pressure rises, the degree of contraction is increased and blood flow remains constant. (2) If the renal blood flow rises, more sodium is present in the fluid in the distal tubules because the filtration rate increases. This rise in the sodium level stimulates the secretion of renin from the JGA with the formation of angiotensin, causing the arterioles to constrict and blood flow to be reduced. (3) If systemic blood pressure rises, the renal blood flow remains constant because of the increased viscosity of the blood. Normally, the interlobular arteries have an axial (central) stream of red blood cells with an outer layer of plasma so that the afferent arterioles skim off more plasma than cells. If the arteriolar blood pressure rises, the skimming effect increases, and the more densely packed axial flow of cells in the vessels offers increasing resistance to the pressure, which has to overcome this heightened viscosity. Thus, the overall renal blood flow changes little. Up to a point, similar considerations in reverse apply to the effects of reduced systemic pressure. (4) Changes in the arterial pressure modify the pressure exerted by the interstitial (tissue) fluid of the kidney on capillaries and veins so that increased pressure raises, and decreased pressure lowers, resistance to blood flow.

The renal blood flow is greater when a person is lying down than when standing; it is higher in fever; and it is reduced by prolonged vigorous exertion, pain, anxiety, and other emotions that constrict the arterioles and divert blood to other organs. It is also reduced by hemorrhage and asphyxia and by depletion of water and salts, which is severe in shock, including operative shock. A large fall in systemic blood pressure, as after severe hemorrhage, may so reduce renal blood flow that no urine at all is formed for a time; death may occur from suppression of glomerular function. Simple fainting causes vasoconstriction and reduced urine output. Urinary secretion is also stopped by obstruction of the ureter when back pressure reaches a critical point.

Glomerular pressure. The importance of these various vascular factors lies in the fact that the basic process occurring in the glomerulus is one of filtration, the energy for which is furnished by the blood pressure within the glomerular capillaries. Glomerular pressure is a function of the systemic pressure as modified by the tone (state of constriction or dilation) of the afferent and efferent arterioles, as these open or close spontaneously or in response to nervous or hormonal control.

In normal circumstances glomerular pressure is believed to be about 45 millimetres of mercury (mmHg), which is a higher pressure than that found in capillaries elsewhere in the body. As is the case in renal blood flow, the glomerular filtration rate is also kept within the limits between which autoregulation of blood flow operates. Outside these limits, however, major changes in blood flow occur. Thus, severe constriction of the afferent vessels reduces blood flow, glomerular pressure, and filtration rate, while efferent constriction causes reduced blood flow but increases glomerular pressure and filtration.

FORMATION AND COMPOSITION OF URINE

The urine leaving the kidney differs considerably in composition from the plasma entering it (Table 1). The study of renal function must account for these differences; *e.g.,* the absence of protein and glucose from the urine, a change in the pH of urine as compared with that of plasma, and the high levels of ammonia and creatinine in the urine, while sodium and calcium remain at similar low levels in both urine and plasma.

Table 1: Relative Composition of Plasma and Urine in Normal Men

	plasma g/100 ml	urine g/100 ml	concentration in urine
Water	90–93	95	—
Protein	7–8.5	—	—
Urea	0.03	2	× 60
Uric acid	0.002	0.03	× 15
Glucose	0.1	—	—
Creatinine	0.001	0.1	× 100
Sodium	0.32	0.6	× 2
Potassium	0.02	0.15	× 7
Calcium	0.01	0.015	× 1.5
Magnesium	0.0025	0.01	× 4
Chloride	0.37	0.6	× 2
Phosphate	0.003	0.12	× 40
Sulfate	0.003	0.18	× 60
Ammonia	0.0001	0.05	× 500

A large volume of ultrafiltrate (*i.e.,* a liquid from which the blood cells and the blood proteins have been filtered out) is produced by the glomerulus into the capsule. As this liquid traverses the proximal convoluted tubule, most of its water and salts are reabsorbed, some of the solutes completely and others partially; *i.e.,* there is a separation of substances that must be retained from those due for rejection. Subsequently the loop of Henle, distal convoluted tubule, and collecting ducts are mainly concerned with the fine control of water and electrolyte balance (Figure 6).

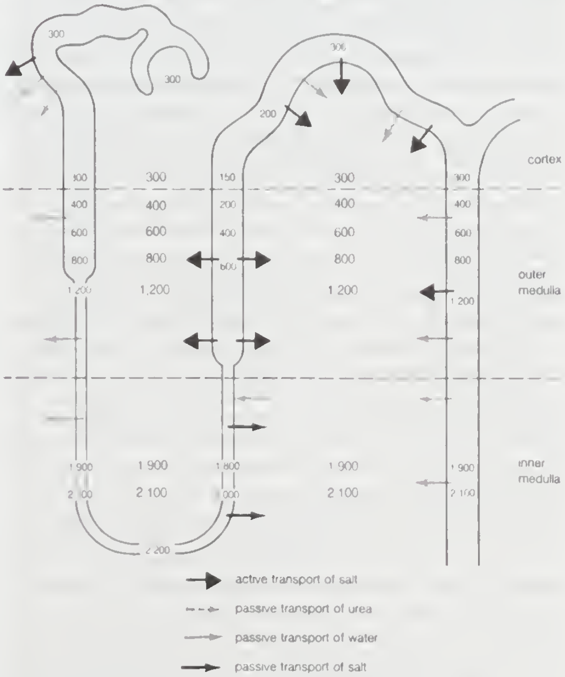

Figure 6: The modes of action of the countercurrent mechanism for concentrated urine production. The values indicated are given in mosmoles of solute/kilogram.

Glomerular filtration. Urine formation begins as a process of ultrafiltration of a large volume of blood plasma from the glomerular capillaries into the capsular space, colloids such as proteins being held back while crystalloids (substances in true solution) pass through. In humans, the average capillary diameter is five to 10 micrometres (a micrometre is 0.001 millimetre). The wall of each loop of capillaries has three layers (Figure 7). The inner layer

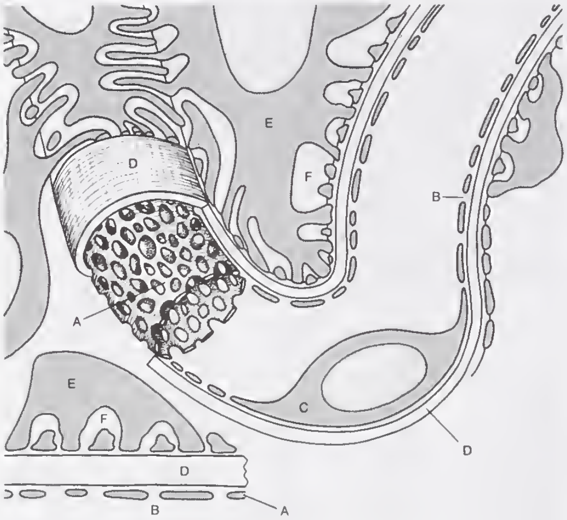

Figure 7: The structure of the human glomerulus, depicting (A) the fenestrated capillary endothelium; (B) fenestrae; (C) an endothelial cell; (D) the basement membrane; (E) a podocyte; and (F) a pedicel.

From J M Forrester, R. Passmore, and J S Robson (eds), *A Companion to Medical Studies*, vol 1, 3rd ed (1985), Blackwell Scientific Publications Ltd

consists of flat nucleated endothelial cells arranged to form numerous pores, or fenestrae, 50–100 nanometres in diameter (a nanometre is 0.000001 millimetre), which allow the blood to make direct contact with the second layer, a basement membrane. The basement membrane of the capillaries, similar to that which occurs in the lining of many other structures and organs, is a continuous layer of hydrated collagen and glycopeptides. Although once thought to be homogeneous, it appears to consist of three layers that differ in the content of polyanionic glycopeptides. The membrane is negatively charged (anionic), owing to its relatively high content of sialic and aspartic acids. Also present are glycosaminoglycans, such as heparin sulfate. The third, external layer consists of large epithelial cells called podocytes (Figure 8). These cells make contact with the outer surface of the basement membrane by slender cytoplasmic extensions called pedicels (foot processes). These processes are slightly expanded at their point of contact with the basement membrane and are separated from each other by slitlike spaces about 20 to 30 nanometres across. A fine membrane (slit diaphragm) closes the slitlike spaces near the basement membrane.

Passage of filtrate

There are two physical processes by which glomerular filtrate may pass the barrier of the glomerular wall—simple diffusion and bulk flow. In bulk flow, the solute in the glomerular filtrate with water passes through pores in the basement membrane. In either case the ultimate restriction to the passage of filtrate appears to lie in the hydrated gel structure of the basement membrane. The negative electrostatic charge in the membrane is an additional restrictive force for negatively charged anionic macromolecules, such as albumin (molecular weight 69,000), while larger protein molecules are restricted by size alone. On the other hand, proteins of smaller molecular size—*e.g.*, neutral gelatin (35,000)—pass through freely. It is possible that the endothelial cell layer may also help to exclude very large molecules and blood cells and that a similar effect is exerted by the slit pores and diaphragm.

The normal process of glomerular filtration depends upon the integrity of the glomerulus, which in turn depends upon its proper nutrition and oxygenation. If glomeruli are damaged through disease or lack of oxygen they become more permeable, allowing plasma proteins to enter the urine. Special cells that may be concerned with the formation and maintenance of the basement membrane of the glomerular walls are called mesangial cells. These lie between loops of the glomerular capillaries and form a stalk or scaffolding for the capillary network. They are themselves embedded in a matrix of glycosaminoglycan similar to that of the glomerular capillary basement membrane and may be responsible for its formation. The mesangial cells are also responsible for ridding the basement membrane of large foreign molecules that may be held there in the course of certain diseases. These cells proliferate and the mesangial matrix enlarges in the course of immunologically induced diseases affecting the glomerulus (see below *Glomerulonephritis*).

Tubule function. The role of the tubules may be assessed by comparing the amounts of various substances in the filtrate and in the urine (Table 2).

General function of tubules

It is apparent that the filtrate must be modified in the tubules to account for the differing compositions of filtrate and final urine; *e.g.*, to allow for the total absence of glucose in the latter, the much smaller volume of urine than filtrate, or for the acidity of urine compared with the neutrality of the filtrate.

As the filtrate passes along the proximal tubule, most of its water and salts are reabsorbed into the blood of the network of capillaries around the tubules. Of other substances, some are reabsorbed completely, others in part, because this portion of the nephron separates substances that must be retained in the body from those destined for excretion in the urine. The function of the proximal tubule is essentially reabsorption of filtrate in accordance with the needs of homeostasis (equilibrium), whereas the distal part of the nephron and collecting duct are mainly concerned with the detailed regulation of water, electrolyte, and hydrogen-ion balance. All of these processes occur in the tubules through both chemical and physical means, and all are subject to hormonal regulation. Although the urine normally differs markedly from filtrate, if tubule function is progressively reduced in experimental situations by cooling or poisoning, the urine will come increasingly to resemble the filtrate. Also, the more rapidly filtration occurs, the less time there is for the urine to be modified during its passage through the tubules.

Reabsorption from the proximal tubule. Reabsorption affects all the glucose of the filtrate, up to 70 percent of its water and sodium (the remainder is absorbed in the distal tubule), most of the potassium and chloride ions,

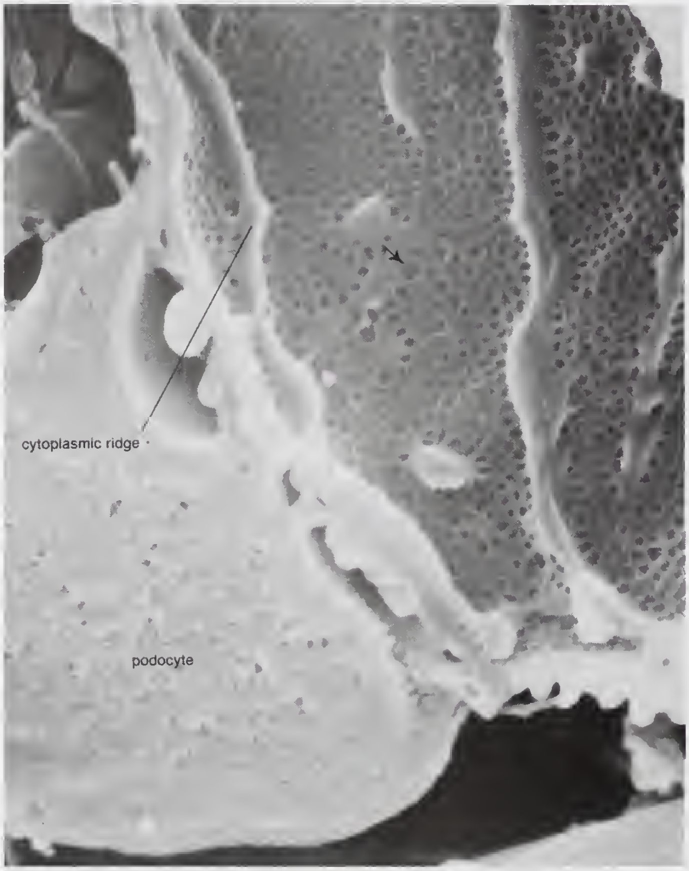

Figure 8: The inner surface of the glomerular endothelium with an associated podocyte. The endothelial cells are characterized by numerous large (500–1000 Å) fenestrae (arrow).

Table 2: Effect of Tubular Reabsorption on Urine
(illustrative 24-hour figures)

	glomerular filtrate	urine	tubular reabsorption (percent)
Water	170 l	1.5	99.1
Glucose	170 g	—	100
Sodium	560 g	5 g	99.1
Chlonde	620 g	9 g	98.5
Phosphate	5.1 g	1.2 g	76.5
Calcium	17 g	0.2 g	98.8
Urea	51 g	30 g	41.4
Sulfate	3.4 g	2.7 g	20.6

some of the uric acid, 40 percent of the urea, and little or none of the sulfate. Of the total solids 75 percent are reabsorbed in the proximal tubule. The first part of the tubule absorbs amino acids, glucose, lactate, and phosphate; the whole convolution absorbs sodium, potassium, calcium, and chloride and, by removing bicarbonate, acidifies the fluid slightly.

The tubule has only a certain capacity for reabsorption. Thus, normally all the glucose arriving in the filtrate is absorbed; but if plasma glucose is increased to high enough levels, the glucose arrives at the tubule cells faster than it can be absorbed—a condition that occurs in diabetes. In other words, there is a critical rate of delivery determined by plasma concentration and filtration rate, and a maximum reabsorptive capacity for each substance in the filtrate. The rate of tubular reabsorption has an upper maximum value that is constant for any given substance. Consequently, if the plasma level rises sufficiently, all surplus of the substance will pass out in the urine; this is true even for glucose, which is totally reabsorbed under normal conditions. On the other hand, the upper maximum value is much lower for phosphate, so there is normally always some phosphate in thc urine. The proximal tubular reabsorption of phosphate is also affected by the phosphate content of the filtrate and is influenced by parathyroid hormone. Phosphate competes with glucose for reabsorption, and its reabsorption is reduced by parathyroid hormone and by vitamin D and is increased, at least for some time, by a high dietary phosphate intake. The amino acids also have their own maximum tubular reabsorption values, but these are high enough to ensure that they are entirely reabsorbed under normal conditions; in certain rare inherited disorders such as cystinuria, in which there is excessive excretion of cystine, their rcabsorption is reduced.

Reabsorption of sodium

The reabsorption of about 70 percent of the sodium ions in the filtrate means that a similar value of water in the filtrate must accompany these ions as a vehicle to prevent a rising osmotic gradient (*i.e.*, to prevent a rising difference in the concentration of the sodium solution inside and outside the tubule). The energy required for the reabsorption of sodium into the blood uses 80 percent of the oxygen consumed by the kidney and represents one-eighth of the oxygen consumption of a person at rest. There is no evidence for active water transport, and the large volume of water reabsorption occurs passively in response to the movement of sodium. Since sodium is quantitatively the major osmotically active solute, the overall effect is to keep the fluid that remains in the tubular lumen, though much reduced in volume, roughly isosmotic with the original glomerular filtrate.

The active reabsorption of sodium (a positively charged ion) into the blood leaves the fluid remaining in the proximal tubule electronegative with respect to the peritubular fluids. This provides a driving force for the reabsorptive transport of negatively charged ions such as chloride, bicarbonate, and organic solutes. Reabsorption of neutral molecules such as urea into the blood is also driven by active sodium transport. Because the tubular epithelium is less permeable to urea and creatinine than it is to water or chloride, however, the free passive movement of water out of the tubular lumen leads to a rising luminal concentration of urea (*i.e.*, above the concentration in the original filtrate with plasma). As a result, a smaller proportion of filtered urea or creatinine than of sodium or water is reabsorbed into the blood, resulting in the elimination of a considerable amount in the urine.

Reabsorption from the loop of Henle. About one-third of the volume of the glomerular filtrate enters the descending limb of the loop of Henle. This fluid is isosmotic with plasma. The reabsorptive characteristics of the descending thin limb and those of the bend of the loop differ greatly from those of the ascending thick limb. The thin epithelium lining the thin limb is permeable to water and solute and has no power of active transport. Accordingly, the fluid entering the limb and the bend of the loop acquires the concentration of the fluid of the surrounding interstitial peritubular fluid. In contrast, the thick ascending limb lined by taller cells has low permeability to water and to urea but actively transports sodium and chloride into the peritubular fluid around both limbs. As a result this fluid in the medullary and deep cortical regions of the kidney becomes highly concentrated, reaching concentrations of up to four times that of the plasma (1,200 mosmoles per litre), mainly owing to the accumulation of sodium and chloride. This accumulation of solute, essential to the formation of a concentrated urine, is discussed in further detail below.

Reabsorption from the distal convoluted tubule. The active transport of sodium out of the ascending limb renders the fluid entering the distal convoluted tubule less concentrated than plasma. Active sodium reabsorption continues throughout the whole of the distal tubule, and this extends to thc early part of the collecting duct. As this part of the nephron is relatively impermeable to water, a large concentration gradient of sodium and chloride between the luminal fluid and the plasma is maintained, the concentration of sodium in the tubule being kept well below that of the plasma. The luminal fluid hcre is also markedly electronegative to the surrounding tissues. The mechanism of sodium reabsorption appears to bc directly linked to the secretion of potassium and of hydrogen ions into the tubule from the blood and is grcatly influenced by the hormone aldosterone, which is secreted by the adrenal gland when the body's sodium level is deficient.

The concentration of urine. As alrcady indicatcd, thc loop of Henle is critical to the ability of the kidney to concentrate urine. The high concentration of salt in the mcdullary fluid is believed to bc achicved in the loop by a process known as countercurrent exchangc multiplication. The principle of this process is analogous to the physical principle applicd in thc conduction of hot exhaust gases past cold incoming gas so as to warm it and conscrve heat. That exchange is a passive one; but in the kidney the countercurrent multiplier systcm uses energy to "pump" sodium out of the ascending limb of thc loop into the medullary fluid. From there it entcrs (by diffusion) the filtrate (isotonic with plasma) that is entering the descending limb from thc proximal tubule, thus raising its concentration a little abovc that of plasma. As this luminal fluid in turn reaches the ascending limb, and subsequently the distal tubule, it in turn provides more sodium to be pumped out into the surrounding fluid or blood, if necessary, and transported (by diffusion) back into the descending limb; this concentrating process continues until the osmotic pressure of the fluid is sufficient to balance the resorptive power of the collecting ducts in the medulla, through which all of the final urine must pass. This resorptive capacity in the ducts is regulated by antidiuretic hormone (ADH), which is secreted by the hypothalamus and stored in the posterior pituitary gland at the base of the brain. In the presence of ADH the medullary collecting ducts become freely permeable to solute and water. As a consequence the fluid entering the ducts (en route to the renal pelvis and subsequent elimination) acquires the concentration of the interstitial fluid of the medulla; *i.e.*, the urine becomes concentrated. On the other hand in the absence of ADH the collecting ducts are impermeable to solute and water; thus, the fluid in the lumen, from which some solute has been removed, remains less concentrated than plasma; *i.e.*, the urine is dilute.

Antidiuretic hormone

The secretion of ADH by the hypothalamus and its release from the posterior pituitary is part of a feedback mechanism responsive to the tonicity of plasma. This interrelation between plasma osmotic pressure and ADH output is mediated by specific and sensitive receptors at the base of the brain. These receptors are particularly sensitive to sodium and chloride ions. At normal blood tonicity there is a steady receptor discharge and a steady secretion of ADH. If the plasma becomes hypertonic (*i.e.,* has a greater osmotic pressure than normal), either from the ingestion of crystalloids such as common salt, or from shortage of water, receptor discharge increases, triggering increased ADH output, and more water leaves the collecting ducts to be absorbed into the blood. If the osmotic pressure of plasma becomes low, the reverse is the case. Thus water ingestion dilutes body fluids and reduces or stops ADH secretion; the urine becomes hypotonic, and the extra water is excreted in the urine.

The situation is complex because there are also receptors sensitive to changes in blood volume that reflexively inhibit ADH output if there is any tendency to excessive blood volume. Exercise increases ADH output and reduces urinary flow. The same result may follow emotional disturbance, fainting, pain, and injury, or the use of certain drugs such as morphine or nicotine. Diuresis is an increased flow of urine produced as the result of increased fluid intake, absence of hormonal activity, or the taking of certain drugs that reduce sodium and water reabsorption from the tubules. If ADH secretion is inhibited by the drinking of excess water, or by disease or the presence of a tumour affecting the base of the brain, water diuresis results; and the rate of urine formation will approach the rate of 16 millilitres per minute filtered at the glomeruli. In certain disorders of the pituitary in which ADH secretion is diminished or absent—*e.g.,* diabetes insipidus—there may be a fixed and irreversible output of a large quantity of dilute urine.

Tubular secretion. The only difference between secretory and reabsorptive tubular mechanisms lies in the direction of transport; secretory mechanisms involve the addition of substances to the filtrate from the plasma in the peritubular capillaries. The small amount of secretion that does occur, except for the secretion of potassium and uric acid, takes place in the proximal tubule. Hydrogen ions are also secreted and ammonia is generated, but they are special cases and are discussed below under *Regulation of acid-base balance.* As in the case of reabsorption, secretion occurs both passively and actively against an electrochemical gradient.

Several drugs are actively secreted, and some of these appear to share a common pathway so that they may compete with each other for a limited amount of energy. This may be turned to therapeutic advantage in the case of penicillin, which is eliminated partly by tubular secretion. The drug probenecid, which can be given simultaneously, competes with penicillin at its secretory site and thus helps to raise the level of penicillin in the blood in the treatment of certain infections. Endogenous (originating within the body) compounds that are secreted also include prostaglandins, bile salts, and hippurate. Uric acid derived from nucleoproteins freely passes the glomerular barrier and is normally largely reabsorbed in the proximal tubule. In some circumstances, however, it is also secreted by other parts of the same convoluted tubule.

The secretion of potassium by the distal tubule is one of the most important events in the kidney as its control is fundamental to the maintenance of overall potassium balance. More than 75 percent of the filtered potassium is reabsorbed in the proximal tubule and in the ascending limb of the loop of Henle, and this percentage remains virtually constant, irrespective of how much is filtered. The amount eliminated in the urine, which is ultimately determined by the dietary intake, is controlled by the distal convoluted tubule. In persons consuming a normal diet, probably about 50 percent of the urinary potassium is secreted into the urine by the distal tubules; this amount can be adjusted according to body need. One of the several factors that influence potassium secretion is a hormone secreted by the cortex of the adrenal gland, aldosterone. In the absence of aldosterone and other mineralocorticoids (adrenocortical steroids affecting electrolyte and fluid balance), potassium secretion is impaired, and potentially dangerous amounts can accumulate in the blood. Excess aldosterone promotes potassium excretion.

Regulation of acid-base balance. The cells of the body derive energy from oxidative processes that produce acidic waste products. Acids are substances that ionize to yield free protons, or hydrogen ions. Those hydrogen ions that derive from nonvolatile acids—such as lactic, pyruvic, sulfuric, and phosphoric acids—are eliminated in the urine. The kidney contains transport mechanisms that are capable of raising the concentration of hydrogen ions in the urine to 2,500 times that in the plasma or, when appropriate, lowering it to one-quarter that of the plasma.

Theoretically, acidification of urine could be brought about either by the secretion of hydrogen ions into the tubular fluid or by the selective absorption of a buffer base (a substance capable of accepting hydrogen ions; *e.g.,* filtered bicarbonate). Current evidence indicates that both filtration and secretion are essential to hydrogen ion excretion and that both proximal and distal convoluted tubules are involved.

The bi-carbonate threshold

The bulk of the bicarbonate filtered at the glomerulus is reabsorbed in the proximal tubule, from which it passes back into the peritubular capillaries. This mechanism is designed to keep the normal plasma bicarbonate concentration constant at about 25 millimoles per litre. When the plasma concentration falls below this level, no bicarbonate is excreted and all filtered bicarbonate is reabsorbed into the blood. This level is often referred to as the bicarbonate threshold. When the plasma bicarbonate rises above 27 millimoles per litre, bicarbonate appears in the urine in increasing amounts.

The brush borders of the cells of the proximal tubules are rich in the enzyme carbonic anhydrase. This enzyme facilitates the formation of carbonic acid (H_2CO_3) from CO_2 and H_2O, which then ionizes to hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). The starting point for bicarbonate reabsorption is probably the active secretion of hydrogen ions into the tubular fluid. These ions may be formed under the influence of carbonic anhydrase from CO_2 liberated from oxidation of cell nutrients and H_2O already in the cells. The filtered base, bicarbonate, accepts the hydrogen ions to form carbonic acid, which is unstable and dissociates to form CO_2 and H_2O. The partial pressure of CO_2 in the filtrate rises, and, as CO_2 is highly diffusible, it passes readily from the tubular fluid into the tubular cells and the blood, and the water is either dealt with in the same way or is excreted. In the meantime the proximal tubular cells are actively reabsorbing filtered sodium, which is balanced by the HCO_3^- formed within the cells from the CO_2 generated by the hydrogen ions in the luminal fluid. Thus the bicarbonate actually reabsorbed is not that which was originally the filtrate, but the net effect is the same as if this were the case.

Other bases besides HCO_3^- may buffer the hydrogen ions secreted into the distal tubules; in addition, the ions may combine with ammonia also secreted by the tubules. The most important non-bicarbonate base present in the filtrate is dibasic phosphate (Na_2HPO_4), which accepts hydrogen ions to form monobasic phosphate (NaH_2PO_4). A measure of the amount of hydrogen ion in the urine that is buffered by bases such as bicarbonate and phosphate is made by the titration of urine with strong base until the pH of the plasma from which the filtrate is derived (7.4) is achieved. This is called the titratable acidity of urine and usually amounts to between 20 and 40 millimoles of H^+ per day.

In normal circumstances about two-thirds of the hydrogen ions to be secreted in the urine is in the form of ammonium salts (*e.g.,* ammonium chloride). Ammonia (NH_3) is not present in plasma or filtrate but is generated in the distal tubular cells and passes into the lumen probably by passive diffusion down a concentration gradient. In the lumen the NH_3 combines with hydrogen ions secreted into the tubule to form ammonium ions (NH_4^+), which are then trapped in the lumen because the lipid walls of the tubular cells are much less permeable to the charged than to the uncharged molecules.

It is now known that ammonia is formed from the hydrolysis of glutamine (an amino acid) to form glutamic acid and ammonia by the enzyme glutaminase. A further molecule of ammonia is obtained by the deamination of glutamic acid to form glutaric acid, which is then metabolized. The more acidic the urine is, the greater is its content of ammonium ions; the introduction of hydrogen ions (*e.g.*, from the diet) stimulates production of ammonium by the tubular cells. The ammonium is excreted in the urine as ammonium salts of surplus anions (negative ions) such as chloride, sulfate, and phosphate, thus sparing for retention other cations (positive ions) such as sodium or potassium.

In summary, hydrogen ion secretion can be considered in three phases. The first occurs in the proximal tubule, where the net result is tubular reabsorption of filtered bicarbonate. The second and third phases take place in the distal tubule, where monobasic phosphate and ammonium salts are formed. The total tubular cell secretion of hydrogen ion is therefore the sum of titratable acidity, the amount of ammonium ion excreted, and the amount of bicarbonate ion reabsorbed. The last may be assessed by calculating the amount of bicarbonate filtered (*i.e.*, plasma concentration of bicarbonate × glomerular filtration rate and subtracting any bicarbonate excreted in the urine). Total hydrogen ion secretion normally amounts to 50–100 millimoles per day but may rise considerably above this in disorders associated with excess acid production, such as diabetes.

Volume and composition. The volume and composition of normal urine vary widely from day to day, even in healthy individuals, as a result of food and fluid intake and of fluid loss through other channels as affected by environmental conditions and exercise. The daily volume averages 1.5 litres (about 1.6 quarts) with a range of 1–2.5 litres, but after copious sweating it may fall as low as 500 millilitres, and after excess fluid intake it may reach three litres or more. There is also variation within a 24-hour period. Excretion is reduced in the early hours, maximal during the first few hours after rising, with peaks after meals and during the early stages of exertion. The urine produced between morning and evening is two to four times the night volume. The excessive secretion of urine (polyuria) of chronic renal disease is typically nocturnal.

The volume of urine is regulated to keep plasma osmotic concentration constant, to control the total water content of the tissues, and to provide a vehicle for the daily excretion to the exterior of some 50 grams of solids, mostly urea and sodium chloride. In a man who ingests 100 grams of protein and 10 grams of salt daily, the urine will contain 30 grams of urea and 10 grams of salt; there are many other possible constituents, but they amount to less than 10 grams overall.

Some urinary constituents (Table 3)—the products of metabolism of nitrogenous substances obtained from food—vary widely in relation to the composition of the diet; thus the excretion of urea and sulfate is dependent on the diet-protein content. A high-protein diet may yield a 24-hour output of 17 grams of nitrogen, a low-protein diet of the same calorific value only three to four grams.

The urine is normally clear. It may be turbid from calcium phosphate, which clears if acetic acid is added. Microscopic deposits include occasional casts, vaguely resembling in form the renal tubules from whose lining they have been shed. An ammoniacal smell is the result of decomposition of urea to ammonia by bacteria and is commonly present on babies' diapers. Certain foods and drugs may cause distinctive odours. The colour of urine depends on its concentration but is normally a bright clear yellow from the pigment urochrome, an end product of protein metabolism. There are also traces of other pigments: urobilin and uroerythrin. The colour may be influenced as well by food dyes, beetroot, and certain drugs.

Table 3: Some Urine Constituents (g/24 hours)

Urea	25–30
Uric acid	0.6–0.7
Creatinine	1.0–1.2
Hippuric acid	0.7
Ammonia	0.7
Amino acids	3.0
Sodium	1–5 (NaCl 15.0)
Potassium	2–4
Calcium	0.2–0.3
Magnesium	0.1
Chloride	7
Phosphate	1.7–2.5
Sulfate	1.8–2.5

The specific gravity of urine may vary between 1.001 and 1.04 but is usually 1.01–1.025. Such variation is normal, and a fixed low specific gravity is an indication of chronic renal disease. If fluid intake is stopped for 24 hours, even a normal kidney will secrete urine with a specific gravity of at least 1.025. There is a limit to the concentrating powers of the kidney, so that the urine is rarely more than four times as concentrated as plasma. In order to excrete their normal solute load, the kidneys need a minimum water output of 850 millilitres as a vehicle; this volume is often called the minimum obligatory volume of urine. If this is not available from intake it has to be withdrawn from the tissues, causing dehydration; but the usual intake is well above the minimum and the urine is rarely at its maximum possible concentration. The reaction of the urine is usually acid, with an overall range of pH 4 to 8 (lemon pie has a pH of 2.3; the value 8 is slightly alkaline, about equal to the pH of a 1 percent solution of sodium bicarbonate).

Abnormal constituents of urine

Foreign proteins of molecular weight less than 68,000 are excreted in the urine, while those of the plasma are retained in the body. If, however, the kidneys are damaged by disease or toxins, the glomeruli will transmit some of the normal serum albumin and globulin and the urine will coagulate on warming. Normally, the urine contains only very small amounts of protein (less than 50 milligrams per 24 hours); however, protein content in the urine is increased after exercise, in pregnancy, and in some persons when standing (orthostatic albuminuria). The protein loss may be greatly increased in certain chronic renal diseases; in the nephrotic syndrome it may even reach 50 grams in a 24-hour period. Certain specific and easily identifiable proteins appear in the urine in diseases associated with the overgrowth of cells that make immunoglobulins.

Glucose is found in the urine in diabetes mellitus. In some healthy persons, however, there may also be an abnormal amount of glucose in the urine because of a low threshold for tubular reabsorption, without any disturbance of glucose metabolism. Lactosuria (abnormal amount of lactose in the urine) may occur in nursing mothers. Ketone bodies (acetone, acetoacetic acid) are present in traces in normal urine but in quantity in severe untreated diabetes and in relative or actual carbohydrate starvation; *e.g.*, in a person on a high-fat diet.

The urine may contain hemoglobin or its derivatives after hemolysis (liberation of hemoglobin from red blood cells), after incompatible blood transfusion, and in malignant malaria (blackwater fever). Fresh blood may derive from bleeding in the urinary tract. Bile salts and pigments are increased in jaundice, particularly the obstructive variety; urobilin is greatly increased in certain diseases such as cirrhosis of the liver.

Porphyrins are normally present only in minute amounts but may be increased in congenital porphyria, a disease characterized by sensitivity to sunlight or by insanity. The presence of porphyrins also may increase after ingestion of sulfonamides and some other drugs.

The normally small quantities of amino acids in the urine may be much increased in advanced liver disease, in failure of tubular reabsorption, and in certain diseases due to inborn errors of protein metabolism. Phenylketonuria, a disease identified by the presence of phenylpyruvic acid in the urine, is due to lack of the enzyme phenylalanine hydroxylase, so that phenylalanine is converted not to tyrosine but to phenylpyruvic acid. The presence of this acid in blood and tissues causes mental retardation; if the urine of every newborn infant is tested, restriction of phenylalanine in the diet in such cases may be beneficial. Alkaptonuria, a disease identified by the presence of homogentisic acid in the urine, is due to lack of the enzyme that catalyzes the oxidation of homogentisic acid; deposits of the acid in the tissues may cause chronic arthritis or spinal disease. Other such disorders are cystinuria, the presence of the amino acid cystine in the urine, when the bladder may contain cystine stones; and maple syrup disease, another disorder involving abnormal levels of amino acid in the urine and blood plasma.

URINE COLLECTION AND EMISSION

Passage of urine from nephron to bladder

From the nephrons the urine enters the final 15 or 20 collecting tubules that open on to each papilla of the renal medulla, projecting into a minor calyx. These open into two or three major calyxes, and these in turn open into the renal pelvis, the upper expanded portion of the ureter.

Urine is passed down the channel of the renal pelvis and ureter by a succession of peristaltic waves of contraction that begin in the muscle fibres of the minor calyxes, travel out to the major calyxes and then along the ureter every 10–15 seconds. Each wave sends urine through the ureteric orifice into the bladder in discontinuous spurts; these can be seen through a cystoscope if a dye is injected into the bloodstream. Gravity aids this downward flow, which is faster when one is standing erect. Though the overall picture suggests that there is a pacemaker (a set of specialized cells capable of rhythmic contractions) near the pelviureteric junction, this has never been satisfactorily demonstrated in the tissue. The pressure in the renal pelvis is normally low, but the smooth muscle coat of the ureter is a powerful one and the pressure above an obstructed ureter may rise as high as 50 millimetres of mercury. The ureters are doubly innervated from the splanchnic nerves above and the hypogastric network below.

The bladder. The bladder is a hollow organ of variable capacity, with a powerful intermediate muscle coat that empties the organ when it contracts, and two muscular sphincters that keep the exit closed at all other times. This smooth muscle coat constitutes the powerful detrusor muscle. At the base of the bladder the region of the bladder neck, or trigone, is demarcated by the two ureteric orifices and the internal opening of the urethra. Muscle fibres loop around the urethral opening to form the internal sphincter, which is under involuntary control. The external sphincter consists of two striated muscles under voluntary control: the compressor urethrae, which surrounds the membranous urethra, and the pair of bulbocavernosus muscles.

The mucous membrane lining the bladder is distensible; it is ridged in the empty organ and smoothed out in distension. In micturition the longitudinal muscle of the bladder shortens to widen the bladder neck and allow urine to enter the urethra. The urethra normally contains no urine except during the act of micturition, its walls remaining apposed by muscle tone. In the male, but not in the female, the external sphincter can maintain continence even if the internal sphincter is not functioning.

Innervation of bladder and urethra

The innervation of the bladder and urethra is complex and important. Essentially, there are three groups of nerves: (1) The parasympathetic nerves constitute the main motor supply to the detrusor; they make it contract, raise pressure within the bladder, relax the internal sphincter, and cause emptying. Afferent parasympathetic channels convey impulses from stretch receptors in the bladder wall to higher centres, permitting cognizance of the state of distension of the organ and stimulating the desire to micturate. (2) The sympathetic nerves stimulate closure of the ureteric and internal urethral orifices and contraction of the internal sphincter, and their action on the detrusor is inhibitory; *i.e.,* the effect is to prevent bladder outflow. Thus the sympathetic serves to control the situation in the distending bladder up to the point when evacuation can be deferred no longer. Afferent paths in the sympathetic convey sensations of pain, overdistension, and temperature from the mucosa of the bladder and the urethra. (3) The somatic nerves cause contraction of the external sphincter; their sensory fibres relay information as to the state of distension of the posterior urethra.

Both the parasympathetic nerves and the somatic nerves (pudendal nerve) to the external sphincter relay impulses to the second through fourth sacral segments of the spinal cord, which constitute a reflex centre for the control of bladder function. This centre connects with higher centres in the brain by ascending and descending fibres in the spinal cord.

Bladder function in micturition. Certain reflexes combine to ensure both maintenance of a steady holding state for urine and normal progressive micturition with complete emptying. When the internal pressure of the bladder rises, it contracts; and it also contracts when urine enters the urethra.

Both bladder sphincters are normally closed. As the organ fills with urine, the contractile response of the muscle wall causes a rise in internal pressure. Relaxation then occurs as an active process of adjustment so that the organ may hold its contents at a lower pressure. As urine continues to enter the bladder, this rise and fall of pressure continues in steplike fashion, with the final pressure always gradually rising.

The repeated transient contraction waves at first are small and are not consciously felt; later, stimuli reach the brain and cause pain and a sharp rise of pressure. These later major contractions can be inhibited voluntarily. The desire to micturate begins at around a content of 400 millilitres, but it can be voluntarily overridden until the content reaches 600–800 millilitres, equivalent to a pressure of 100 millimetres of water. Until this point the sphincters remain contracted to keep the urethral exit closed, but eventually the desire to micturate becomes urgent and irrepressible. Until that time, voluntary inhibition of the detrusor and contraction of the perineal muscles have kept the internal pressure as low as possible and have prevented efflux. The threshold is dependent to some extent on the rate of filling and is higher when filling is slow; and training affects the amount the bladder can retain. In young children the situation is less controllable, and even small amounts of urine may excite reflex evacuation. Emotional influences are important. Anxiety inhibits the capacity of the bladder to relax on filling, so that under conditions of stress there may be some involuntary passage of small quantities of urine.

Normal micturition

Micturition. Micturition is a complex activity, partly reflex and unconscious and mediated by the lower spinal cord centres, and partly under conscious control by the higher centres of the brain. Voluntary micturition begins with willed messages from the brain that reach the bladder via the motor fibres of the pelvic nerves to stimulate the detrusor, at the same time actively relaxing both urethral sphincters. But the reflexes already mentioned ensure that, once the process has begun and urine has entered the urethra, the contraction of the detrusor will continue and the sphincters will remain relaxed until evacuation is complete and the bladder empty. Evacuation is aided by voluntary contraction of a wide range of accessory muscles. The muscles of the abdominal wall contract to increase pressure on the bladder from without; the diaphragm descends and the breath is held; at the same time there is relaxation of the muscles of the perineal floor. Thus voluntary initiation and control of micturition is effected partly by an active process of stimulating parasympathetic sacral nerve outflow, partly by removing the normal inhibition exerted by the higher centres on the reflex centres in the spinal cord. Once begun, micturition is carried through to completion by lower and higher centres acting in concert; sensory messages from the urine-distended urethra also play a part. It follows that even if a bladder is not particularly distended and if reflex emptying is not urgent, the bladder can nevertheless be evacuated by voluntary contraction of the abdominal wall, so initiating the reflex process that, once begun, takes over.

TESTS OF RENAL FUNCTION

Quantitative tests. Important quantitative tests of renal function include those of glomerular filtration rate, renal clearance, and renal blood flow. Tests are also made to estimate maximal tubular activity, tubular mass, and tubular function. Radiological and other imaging methods are useful noninvasive diagnostic techniques, and renal biopsy is valuable in detecting pathological changes that affect the kidneys. In both clinical and experimental studies one of the most fundamental measures of renal function is that of the glomerular filtration rate (GFR). The GFR is calculated by measuring the specific clearance from the body of a substance believed to be excreted solely by glomerular filtration. The renal clearance of any substance is the volume of plasma containing that amount of the substance that is removed by the kidney in unit time (*e.g.*, in one minute). Clearance, or the volume of plasma cleared, is an artificial concept since no portion of the plasma is ever really cleared in this fashion.

Renal clearance

It was soon realized, however, that if a substance could be found that was freely filtered by the glomeruli and was neither reabsorbed, metabolized, nor secreted by the renal tubules, its clearance would equal the GFR. This is so in these circumstances because the amount of such a substance excreted in the urine in one minute would equal the amount that has been filtered at the glomeruli in the same time. If the concentration of the substance in the plasma (which is the same as that in the glomerular filtrate) is known, the clearance volume must represent the volume of glomerular filtrate.

The first substance identified to be excreted in this way was the polysaccharide inulin (molecular weight about 5,000), which is extracted from the roots of dahlias. Although inulin is not naturally found in human plasma it is nontoxic and can be injected or infused into the bloodstream. Its concentration also can be measured readily and accurately. In the adult male the GFR is 125 millilitres per minute per 1.73 square metres of body surface. In the adult female, the values are about 85 percent of those for the same standard area of body surface. Inulin clearance is now accepted as the standard for estimation of the GFR.

Clearance value is not the same as excretion rate. The clearance of inulin and some other compounds is not altered by raising its plasma concentration, because the amount of urine completely cleared of the agent remains the same. But the excretion rate equals total quantity excreted per millilitre of filtrate per minute, and this value is directly proportional to its plasma concentration.

Substances, such as urea, whose clearance is less than the GFR must be reabsorbed by the renal tubules, while substances whose clearance is greater than the GFR must be secreted by the renal tubules. Since the discovery of inulin, researchers have identified a small number of other substances that are excreted by the kidney in a similar fashion and that have similar clearance values. These include vitamin B_{12}, circulating free in plasma and unbound to protein, and sodium ferrocyanide.

The clearance of creatinine was used as a measure of renal function before inulin was discovered; because this substance is found naturally in plasma, creatinine clearance is still widely used as an approximate measure of the GFR. Creatinine is produced in the body at virtually a constant rate, and its concentration in the blood changes little; accordingly, creatinine clearance is usually measured over a period of 24 hours. There is evidence that in humans creatinine is secreted into the urine by renal tubules as well; however, the amount is small and constant and has little effect on the measure of the GFR.

The concept of clearance is also useful in the measurement of renal blood flow. Para-aminohippuric acid (PAH), when introduced into the bloodstream and kept at relatively low plasma concentrations, is rapidly excreted into the urine by both glomerular filtration and tubular secretion. Sampling of blood from the renal vein reveals that 90 percent of PAH is removed by a single circulation of blood through the kidneys. This high degree of PAH extraction by the kidney at a single circulation implies that the clearance of PAH is approximately the same as renal plasma flow (RPF). The 10 percent of PAH that remains in renal venous blood is conveyed in blood that perfuses either nonsecretory tissue, such as fibrous tissue or fat, or parts of the tubule that do not themselves secrete PAH. In practice this small remaining percentage is usually ignored, and the clearance of PAH is referred to as the effective renal plasma flow. In humans PAH clearance is about 600 millilitres per minute, and thus true renal plasma flow is about 700 millilitres per minute.

Estimation of the GFR and RPF allows the proportion of available plasma perfusing the kidney that is filtered by the glomerulus to be calculated. This is called the filtration fraction and on average in healthy individuals is 125/600, or about 20 percent. Thus about one-fifth of plasma entering the glomeruli leaves as filtrate, the remaining four-fifths continuing into the efferent glomerular arterioles. This fraction changes in a number of clinical disorders, notably hypertension.

Filtration fraction

Reference has already been made to the fact that the renal tubules possess a limited capacity to perform certain of their functions. This is the case, for example, in their ability to concentrate and dilute urine and to achieve a gradient of hydrogen ions between urine and blood. Concentrating power can be tested by depriving the individual of water for up to 24 hours, or, more simply, by introducing a synthetic analogue of ADH into each nostril. The water deprivation test assesses the individual's capacity to produce ADH and the sensitivity of the renal concentrating mechanism to circulating ADH. The use of an analogue of ADH assesses only the sensitivity of the renal tubules to the hormone.

The limits of renal ability to excrete acid and establish a gradient of the concentration of hydrogen ions between plasma and urine has been mentioned above. The power of acidification of urine is best estimated by measuring the pH of urine after the administration of ammonium chloride in divided doses over two or three days. Other specific functions that are tested include the individual's ability to conserve sodium, potassium, and magnesium. In general, these tests are carried out by administering diets that are deficient in these electrolytes and then estimating the minimum rate of excretion after several days.

Radiological and other imaging investigations. Imaging techniques are used to determine the anatomical site, configuration, and level of functioning of the kidneys, pelvis, and ureters. A plain X ray nearly always precedes any other more elaborate investigation, so that the size, outline, and position of the two kidneys, as well as information about the presence or absence of calcium-containing renal stones or zones of calcification can be ascertained. Excretion urography is one of the simplest methods of defining these aspects more precisely, though this radiological method is giving way to noninvasive imaging methods such as ultrasonography and nuclear magnetic resonance (NMR). In excretion urography, the kidneys are observed in X rays after intravenous injection of a radiopaque iodine-containing compound that is excreted largely by glomerular filtration within one hour of the injection. A series of X-ray images (nephrograms) then indicates when the contrast substance first appears and reveals the increasing radiographic density of the renal tissue. The X rays also indicate the position, size, and presence of scarring or tumours in the organs and provide an approximate comparison of function in the two kidneys. Finally the dye collects in the bladder, revealing any rupture or tumour in this organ.

Excretion urography

Obstruction to the flow of urine also may be revealed by distension of the calyceal system above the site of obstruction. This is more clearly detected by urography, in which contrast medium is injected through a fine catheter introduced either directly into the pelvis of the kidney or into the ureteral orifice visualized during cystoscopy. A micturating cystogram involves the injection of contrast substance into the bladder and is of importance in the investigation of urinary tract infection in childhood. It may show the reflux of urine from the bladder upward into the ureters or kidneys on micturition. Because of the risk of radiation to the gonads this test should be conducted only on certain patients.

A radioactive renogram involves the injection of radioactive compounds that are concentrated and excreted by the kidney. The radiation can be detected by placing gamma scintillation counters externally over the kidneys at the back; the counts, transcribed on moving graph paper, yield characteristic time curves for normal and disordered function.

A picture of renal circulation can be obtained by introducing a radiopaque substance directly into the abdominal aorta just above the origin of the renal arteries, or directly into the renal arteries themselves. The contrast material yields a renal angiogram, showing the renal vascular tree. The technique is especially valuable in demonstrating the presence of localized narrowing or obstructions in the circulation or of localized dilatations (aneurysms). Tumours, which tend to be well vascularized, are also distinguishable from cysts, which are not well supplied with blood.

Non-invasive imaging techniques

Ultrasound and NMR have the advantage of being noninvasive and apparently free from risk to the patient. They are useful in detecting tumours of the kidney or adjacent structures and in distinguishing tumours from cysts. Ultrasound techniques are comparatively simple and have replaced other methods in detecting the presence of polycystic kidneys.

Renal biopsy. The visual, usually microscopic, examination of a specimen of kidney tissue removed from a living patient (renal biopsy) is the only investigative method that yields exact histological data on renal structure. The material for examination is usually obtained by inserting a special needle through the skin of the back into the kidney substance and withdrawing a fragment of tissue. A general anesthetic is not usually required, the procedure occupying only a few minutes. Renal biopsy has been valuable in clarifying several renal disorders, notably those affecting the glomeruli, and in revealing their prognosis and natural course. The only serious potential complication is excessive bleeding, but this is rare. The procedure is not justified, however, if the patient possesses only one kidney or suffers from a bleeding disorder or from severe, uncontrolled high blood pressure.

THE ROLE OF HORMONES IN RENAL FUNCTION

Certain hormones and hormonelike substances are intimately related to renal function. Some of these, such as ADH (or vasopressin), are produced outside the kidney and travel to the kidney via the blood as chemical messengers. Others are produced within the kidney and appear to exert only a local effect. The role of ADH in controlling diuresis has already been discussed. ADH regulates water excretion by increasing the permeability of the collecting ducts to water and salt and by accelerating water and ion transfer in a direction determined by the osmotic gradient. The receptors at the base of the brain form part of the feedback mechanism that (1) stimulates ADH output if the osmotic concentration of extracellular fluid (ECF) is high, so as to concentrate the urine, and (2) reduces ADH output and so dilutes the urine if osmotic concentration of ECF and of plasma falls.

Hormones of the adrenal cortex

The hormones of the adrenal cortex are also important in influencing renal function, directly or indirectly. In stress situations, as after an injury or a surgical operation, the output of hydrocortisone and other corticosteroids is increased because the adrenals are stimulated by adrenocorticotropin (ACTH), a secretion of the pituitary gland. Hydrocortisone increases protein breakdown, and consequently the output of nitrogen in the urine, and affects water metabolism; lack of hydrocortisone reduces the power of the kidney to deal with normal water loads. The hormone also promotes sodium retention and loss of potassium and hydrogen ions by the kidney. Aldosterone influences electrolyte metabolism by facilitating the reabsorption of sodium ions at the distal tubules, also at the expense of hydrogen and potassium excretion. The action of aldosterone has been described as priming the sodium reabsorption pump; it is the adrenal hormone most important to tubular function. It also influences the ability of the bowel to absorb sodium, and thus its level of production profoundly influences overall sodium balance. Deficiency of aldosterone allows a steady loss of sodium in the urine, causing a fall in blood pressure that may result in fainting.

The action of the parathyroid glands is to increase blood calcium by mobilizing calcium from the bones and other sourccs; if this hormone functions to excess, as in tumours of the glands, the urinary loss of calcium is much increased and calcium stones tend to form in the kidneys and the bladder. Parathyroid hormone also increases the renal excretion of phosphate and accelerates the conversion of hydroxylated vitamin D to the dehydroxylated form in the kidney. The pituitary growth hormone facilitates protein synthesis and decreases the urinary loss of nitrogen. The sex hormones estrogen and progesterone exert an ill-defined activity as regards salt and water metabolism.

Renin–angiotensin system

The juxtaglomerular apparatus (JGA), consisting of an asymmetrical cuff of large granular cells in the wall of the afferent arteriole near its entry into the capsule of the nephron, contains renin in the granules in the cells. Renin is a true internal secretion of the kidney. Entering the plasma, it acts as an enzyme that induces one of the plasma globulins to yield angiotensin I, which is inactive, and which gives rise in turn to angiotensin II, the most potent agent for constricting the blood vessels and raising the blood pressure. The formation of renin at the JGA is induced by a fall in blood pressure and inhibited by a rise. When the pressure falls, the output of angiotensin II raises the pressure and also excites the release of aldosterone from the adrenal cortex. This process is another example of a feedback mechanism analogous to that controlling the output of ADH.

Prostaglandins

Among the prostaglandins, a group of hormonelike fatty acids synthesized throughout the body, the ones found in the kidney tissues appear to exert local influence on various aspects of renal function. Unlike true hormones, prostaglandins are not transported away from their site of origin by the blood. The interstitial and collecting duct cells of the kidney produce a characteristic prostaglandin, PGE_2, and the renal cortex produces PGI_2, or prostacyclin. Renal prostaglandins interact with the renin–angiotensin system in several ways. The renal cortex prostaglandin PGI_2 mediates the increased release of renin in response to decreases in renal blood flow. The angiotensin subsequently formed in the plasma stimulates production of the interstitial and duct cell prostaglandin (PGF_2), which itself inhibits angiotensin-induced vasoconstriction. For this reason the renal cortex prostaglandin is thought to be an important vasodilator, maintaining renal blood flow when this is threatened (for example, after blood loss). Prostaglandins may also inhibit the action of ADH on the distal tubule and collecting ducts, and the interstitial and duct cell prostaglandin may have a direct effect in inhibiting renal tubular sodium reabsorption; however, the relative importance of these different actions in the healthy human is not known.

Another substance that causes the dilation of blood vessels, the enzyme kallikrein, may also exert an influence on renal blood flow. Kallikrein is secreted by renal tubules and is added to the urine in the distal tubules. It activates the conversion of kininogen to bradykinin, which is also a powerful vasodilator. Bradykinin is inactivated by a kininase, which also converts angiotensin I to angiotensin II, a substance that causes the constriction of blood vessels. Thus the same enzyme that inactivates the vasodilator bradykinin catalyzes the production of the vasoconstrictor angiotensin II. This relationship again suggests a delicately balanced internal control system.

Dopamine is a putative renal hormone that may affect salt balance. The sympathetic nerves that travel to the kidney, the terminals of which release catecholamines such as norepinephrine, are not believed to be important in controlling tubular salt reabsorption. Transplanted human kidneys function adequately despite the lack of any nerve supply and so renal nerves are not essential. However, because dopamine (also a catecholamine released at sympathetic nerve endings) is present in urine in amounts far in excess of the amount that might be filtered from the blood, it may be deduced that some dopamine is formed within the kidney. It is now believed that dopamine is formed enzymatically within the kidney from its precursor, L-dopa, which freely circulates in the blood, and that only small amounts are released by sympathetic nerve endings. Dopamine is a powerful natriuretic substance (*i.e.*, one capable of increasing urinary salt loss) and renal vasodilator. Its role in salt balance, renal function, and blood pressure control remains speculative.

The most recently identified hormone that influences renal function is secreted by special "stretch receptor" cells in the atria of the heart in response to a rise in atrial pressure, as during heart failure. This hormone, called atrial natriuretic peptide (ANP), exerts a vasodilator effect on the kidney and also reduces tubular reabsorption of sodium. Both actions result in increased urinary elimination of salt and water and tend to restore atrial pressure toward the normal. It is probably an important hormone controlling the volume of the extracellular fluid.

BIOLOGICAL CONSIDERATIONS

During most of the pregnancy period the glomerular filtration rate (GFR) is increased by as much as 50 percent, corresponding to an increase in renal blood flow of up to 25 percent in the middle three months of pregnancy. Glycosuria is frequent and is due to increased glucose loading of the filtrate; there is some sodium retention with a tendency to abnormal accumulation of serous fluid (edema), and some protein may appear in the urine. Anatomical changes include enlargement and dilation of the pelvis and ureters, caused by both hormonal action and partial ureteric obstruction by the gravid uterus. These changes may be responsible for the increased susceptibility to urinary tract infection during pregnancy.

The kidneys of the fetus begin to function well before birth, as indicated by a steady rise in the urea and uric acid content of the amniotic fluid in which the fetus exists; the fetus probably swallows fluid and voids it as urine. But even at birth, half the work of excretion is still being carried out via the placental circulation and the maternal kidneys, and this dependence is abruptly curtailed. Kidney function is far from fully developed in the newborn infant. The glomerular filtration rate is only some 30 millilitres per minute per square metre of body surface, compared to 75 in the adult, and tubular function does not attain adult performance until the end of the first year. The 24-hour output of urine is only some 20 millilitres; the output of water and the renal clearance of sodium, potassium, and phosphate is low; the urine is dilute and often contains protein. Because the kidney has such a poor capacity to excrete solids, the infant is exposed to the dehydrating effect of vomiting and diarrhea, which readily induce renal failure.

Rhythms in urine output

There is an increased urine output at the commencement of muscular exercise, due to the general stimulation of circulation, but a later falling off with the fatigue and sweating caused by severe prolonged exertion. The 24-hour rhythm in output has been mentioned. The small output in the early morning hours is a practical convenience to prevent disturbance of sleep. If the natural sleep rhythm is inverted, as by working on night shift, electrolyte and water output follow suit. The urine is acidic at night and becomes less so, or alkaline, on rising. Output is maximal during the first waking hours and rises after meals. Because of all this variation in water and solute output, any analytic study of urine components must be conducted on specimens obtained over a 24-hour period.

(D.LeV./J.S.Ro.)

Excretory system diseases and disorders

The impact of diseases on the elimination of wastes and the conservation of an appropriate amount and quality of body fluid is the primary concern in this section. Many of the manifestations of renal disease can be accounted for in terms of disturbance of these two functions, and the alleviation of symptoms in those renal diseases that cannot yet be cured depends on knowledge of how these two functions are affected.

The eliminatory process does not, of course, end with the formation of urine; the urine has to pass down the ureters to the bladder, be stored there, and voided, usually under voluntary control. The whole mechanism can be deranged by structural changes in the lower urinary tract, by infection, or by neurological disorders that lead to abnormal emptying of the bladder. Disturbance of the lower urinary tract is an important cause of pain and distress, notably during pregnancy and in the elderly; and it can lead to serious and progressive damage to the kidneys, either by interfering with the drainage of urine or by allowing bacterial infection to have access to the kidney.

FUNCTIONAL ASPECTS

Effects of abnormal renal function on body fluid. Renal disease in its diverse forms can lead to bodily deficits or excesses of water, sodium, potassium, and magnesium, and also to protein deficits occasioned by great losses of protein in the urine. Inability of the kidney to function normally may lead to retention in the blood of the waste products of protein metabolism, such as urea and uric acid, and of other nitrogenous compounds such as creatinine. There may be abnormally high levels of phosphates in the blood, which in turn can lead (for reasons about which there is still some disagreement) to low blood levels of calcium. The calcium deficiency can cause tetany, a condition marked by muscular spasms and pain, and calcium may be lost from the bones in the process of restoring normal calcium levels in the blood and tissue fluid. For descriptive purposes, changes in volume, changes in composition, and protein depletion of renal origin will be discussed separately, but these disturbances can and often do coexist.

Though body fluid is most readily apparent in the bloodstream, it is present, and in larger amounts, in the tissues, both between the cells (interstitial fluid) and within them (intracellular fluid). Extracellular fluids, which include interstitial fluid and blood plasma, amount to 25 percent of body weight and contain sodium as their predominant cation (positive ion; metals and hydrogen in solution are cations). Intracellular fluids, amounting to 33 percent of body weight, have potassium as their predominant cation. These various "compartments" of body fluid are in osmotic equilibrium, so that if solute (*e.g.*, sodium chloride) is added to the extracellular compartment so as to increase the concentration of the extracellular solution, water will join it to reduce the concentration, and that compartment will increase. An increase in extracellular fluid, if it is considerable, may be clinically apparent as edema, a swelling of the tissues by fluid, which can usually be displaced by firm pressure. Edema is present in acute inflammation of the kidney (nephritis), in protein deficiency of renal origin, and in chronic nephritis complicated by heart failure associated with abnormally high blood pressure; a factor common to all these states is failure of the kidneys to excrete sodium and water in adequate amounts.

Edema and dehydration

The kidneys in such edematous states need not themselves be diseased; for example, normal kidneys, in a patient with heart failure, may retain sodium when handicapped in their function by poor circulation and by abnormal amounts of sodium-retaining hormones, such as aldosterone. Increase in extracellular fluids is the only volume change that is both common and easily discernible in renal disease, but the opposite condition, sodium depletion or clinical dehydration, is more commonly the result of vomiting and diarrhea when they are complications of terminal renal disease. Sodium and water depletion can be recognized by a lack of elasticity in the superficial tissues and by poor filling of the blood vessels, as well as by signs of impaired circulation, including a fall in blood pressure and an increase in pulse rate. Though changes in intracellular fluid volume occur in some diseases, especially when the potassium content of the body is affected, there is no easy way of detecting them.

Properties of body fluids. Because of the importance of osmotic forces in determining fluid distribution within the body, an important attribute of body fluid is its overall osmotic concentration, or osmolality. This depends on the concentration of solutes. While all solutes contribute to osmolality, small particles such as sodium or chloride ions are influential out of all proportion to their weight, and indeed account for over 90 percent of the osmolality of plasma. In the context of renal disease, changes in osmolality depend largely on how the kidney handles water. When the kidney either is incapable of conserving water or is not stimulated by ADH of the pituitary to do so, water is lost from the body, and a state of water depletion develops, characterized by increasing osmolality of body fluid. At other times, the kidneys may retain too much water, especially when too much hormone is present; in this case, water excess results, giving a clinical state of water intoxication, with decreased osmolality of body fluids.

Change in hydrogen-ion concentration

Another important general property of body fluid is its degree of acidity or alkalinity. The kidneys are involved in the excretion of hydrogen ions, and imperfect function leads to their retention, the state of so-called renal acidosis. Renal acidosis may occur as part of general renal failure or as a specific disease of the renal tubules, one of whose functions is to convert the slightly alkaline glomerular filtrate into the (usually) acidic urine.

Apart from these general changes in body fluid, the pattern of individual constituents can be distorted in renal disease. For many substances, the problem is one of failure of excretion, with consequent increased concentration in body fluids. Insofar as excretion is achieved by filtration, the rise in concentration may assist excretion, permitting prolonged states of balance, at the cost of increased, but often tolerable, levels of concentration. For example, an individual in renal failure must put out as much urea as a healthy individual taking the same diet; but that person can only do so at a blood-urea concentration of 100 milligrams per 100 millilitres, instead of a normal blood-urea of 25 milligrams per 100 millilitres. Substances whose concentration increases in this way include urea, creatinine, uric acid, phosphate, sulfate, urochrome, and indeed all the usual constituents of urine apart from those that are "regulated" rather than simply "excreted." Potassium should be mentioned because of the special danger associated with its retention, which can lead to fatal irregularity of cardiac action. This is a recognized danger of acute renal failure, now commonly prevented by use of the artificial kidney and its semipermeable membranes, and sometimes by the use of resins that will take up potassium in the alimentary tract.

Normal urine contains traces of protein, and in many forms of renal disease there is an increased excretion of protein in the urine, usually representing an increased permeability of the tuft of capillaries forming the glomerulus. This increased proteinuria (often, but less correctly, known as albuminuria) generally amounts to 0.5 gram per day or more. When it exceeds five grams per day and persists at this level, the loss of protein in the urine exceeds the capacity of the liver to produce new protein from the available materials; the concentration of protein in the blood decreases, and this leads to an increasing outflow of fluid from the bloodstream into the tissues (there is normally an equilibrium between the physical pressure in the capillaries, which tends to force fluids out, and the osmotic pressure of plasma proteins, the effect of which is to hold fluid in). This balance of forces is upset by a deficit of plasma proteins. The general loss of fluid into the tissues leads to massive edema, to which the kidneys contribute further by retaining salt and water. The combination of high levels of protein in the urine, low protein levels in the blood, and consequent edema is known as the nephrotic syndrome. This is a good example of a syndrome, defined as a recognizable pattern of manifestations that has not one but a number of possible causes. Other examples of syndromes in renal disease are acute renal failure and chronic renal failure.

Disorders of urine flow. If little or no urine appears, it may be because the kidneys are forming little urine (oliguria) or none (anuria); or it may represent a holdup in the bladder or urethra affecting the outflow from both kidneys. About one person in 500 is born with only one kidney, and loss of a kidney from disease or accident is not rare. In such cases, patients with complete obstruction to the remaining ureter will experience the same effect as in obstruction of the entire lower urinary tract. Partial or complete failure to form urine is treated in the section on acute renal failure, obstructive conditions in the section on diseases of the urinary tract. (D.A.K.B./J.S.Ro.)

Damage to nervous control

In instances of damage to nervous control, certain typical clinical situations may be differentiated, corresponding to different modes of disordered urinary flow: (1) Lack of conscious inhibition of micturition because of damage to the cerebral cortex or, more commonly, from psychological causes results in a need to micturate that cannot be suppressed even though the bladder volume may be quite small; micturition is precipitate and continues until the bladder is empty. (2) Transverse lesions or other damage to the spinal cord above the sacral reflex centres that cause paralysis of the lower half of the body produce at first a bladder that is atonic (lacking in physiological tone). This bladder becomes greatly distended; the detrusor relaxes and reflex micturition is abolished. Pressure finally rises sufficiently to overcome the spasm of the sphincters and urine is voided in small amounts. Further accumulation and partial voiding of the overflow recur (overflow incontinence). Under these conditions the bladder readily becomes inflamed, which may cause disability or death from chronic ascending urinary infection. A catheter may be inserted or firm pressure on the lower abdominal wall may be used to avoid overdistension and to develop an "automatic" bladder after some time. This is a small capacity organ (around 150 millilitres) with frequent emptying; there is reflex control mediated through the sacral segments of the spinal cord; the higher centres do not restrain the detrusor, and the internal sphincter relaxes more readily. Voluntary assistance from the abdominal muscles helps in this situation if these too have not been paralyzed. There is, however, always some residual urine from incomplete emptying and a risk of infection. (3) In contrast, there is the isolated, or "autonomous," bladder resulting from damage to the central nervous system below the sacral cord reflex centres or to the nerves supplying the bladder and urethra. The bladder becomes tense but contracts only weakly so that, while small amounts of urine are voided, the residual urine may be as high as 200–300 millilitres. This condition is known as active incontinence as opposed to the overflow incontinence of the automatic bladder. Here again, active support from the abdominal muscles is helpful. (D.LeV./J.S.Ro.)

Dysuria

Pain associated with urination (dysuria) can arise from bladder distension, which is then relieved by effective micturition; from inflammation of the lower urinary tract, commonly due to infection but rarely caused by chemical irritants in the urine; and from mechanical irritation by tumour or during the passage of stones. Dysuria is commonly, but not necessarily, associated with frequency of urination. This in turn may represent either an irritable or contracted bladder; or the actual amount of urine formed may be unusually large (polyuria), in which case voiding is likely to be painless. Sometimes polyuria may not be noticed by day but may manifest itself in the need to micturate on several occasions during the night (nocturia). The acute onset of dysuria and frequency suggests urinary infection; sustained polyuria is more likely to be due to renal failure (defective concentrating power) or to diabetes. In those who drink beverages into the night, nocturia is physiological.

Incontinence of urine

Incontinence, the involuntary passage of urine (or feces), may be due to a faulty nerve supply, which either leaves the sphincters relaxed or allows them to be overcome by distension of the bladder. Comatose and disturbed patients, especially among the elderly, are commonly incontinent. Apart from nerve lesions, the sphincters that normally prevent the escape of urine may be damaged by repeated childbirth, by the growth of the prostate, or by other distortions of the bladder neck. Procedures have been devised to stimulate the sphincters electrically, when their nerve supply is damaged; or to stimulate the bladder to empty itself at set times. For chronic incontinence, however, devices to catch the urine and prevent soiling of clothing are the most practical.

DISEASES AND DISORDERS OF THE KIDNEY

In this section, attention is directed not only to specific diseases of the kidney but also to the syndromes of acute and chronic renal failure, which have multiple causes. Infective disorders of the kidney are dealt with later, as part of the general problem of infection of the urinary tract.

Acute renal failure. Acute renal failure occurs when renal function suddenly declines to very low levels, so that little or no urine is formed, and the substances, including even water, that the kidney normally eliminates are retained in the body. There are two main mechanisms that can produce acute renal failure. When the cardiac output—the amount of blood pumped into the general circulation by the heart—is lowered by hemorrhage or by medical or surgical shock, the renal circulation is depressed to an even greater extent. This leads directly to inefficient excretion, but, more importantly still, the kidney tissue cannot withstand prolonged impairment of its blood supply and undergoes either patchy or massive necrosis (tissue death). Given time, the kidney tissue may regenerate, and it is on this hope that the treatment of acute renal failure is based. The form of acute renal failure that is due to a poor supply of blood (ischemia) has many causes, the most common and most important being multiple injuries, septicemia (infections invading the bloodstream), abortion with abnormal or excessive bleeding from the female genital tract, internal or external hemorrhage, loss of fluid from the body as in severe diarrhea or burns, transfusion reactions, and severe heart attacks; a special case is the transplanted kidney, which commonly goes through a phase of acute renal failure that is independent of possible rejection.

Renal failure due to poisons

The second common mechanism of acute renal failure is toxic. Many poisons are excreted by the kidney, and in the process, like other urinary constituents, they become concentrated and thus reach levels in the tubular fluid that damage the lining cells of the tubules. Though the tubular cells die and are shed in the urine, regeneration can take place and the patient survive, if he can be maintained during the period of depressed renal function and is not killed by other effects of the poison. Poisons that can affect the kidney in this way are numerous, but the main groups are heavy metals (mercury, arsenic, uranium); organic solvents (carbon tetrachloride, propylene glycol, methanol); other organic substances (aniline, phenindione, insecticides); and antibacterial agents (sulfonamides, aminoglycosides, amphotericin), and some fungi (*e.g., Amanita phalloides*). In addition to the ischemic and toxic causes of acute renal failure, mention must be made of fulminating varieties of acute renal illnesses that are generally mild (*e.g.,* acute glomerulonephritis—see below) and of the acute form of immunologic rejection that can destroy a kidney irrevocably within minutes of transplantation. Acute obstruction to the flow of urine from the kidneys obviously also can imperil renal function.

The course of acute renal failure can usefully be divided into three phases: an onset phase, a phase of established acute renal failure, and a recovery phase. In general, but not invariably, the second of these phases is characterized by a low output of urine (oliguria) and the third by an increasing urine output (polyuria). The onset phase is dominated by general illness, in which the episode of acute renal failure arises; at this stage there may be evidence of threatened renal damage such as blood in the urine or pain in the loins. At this early stage, renal damage may be reversible by prompt treatment of circulatory failure (*e.g.,* by the transfusion of adequate amounts of plasma, whole blood, or electrolyte replacement fluids) and by maintaining adequate blood oxygen levels. Infection or any underlying causative disorder also must be treated quickly.

Renal failure: second phase of clinical course

In the second phase, small amounts of urine, often containing red blood cells, or hemoglobin, are passed; complete absence of urine is not common and suggests that an obstruction is preventing urine from being passed. In quantitative terms, a urine volume of less than 500 millilitres per day constitutes significant oliguria; this is the least amount in which the excretory demand imposed by an ordinary diet can be met. In the actual situation of acute renal failure, the excretory demands may in fact be much greater, since many of the causes of acute renal failure also are causes of increased breakdown of the tissues in general. The blood urea increases, the rate of increase being conditioned both by the degree of renal failure and by the amount of tissue breakdown. Besides nitrogen, the kidney can no longer excrete adequate amounts of water, sodium, and potassium.

These various inadequacies point the way to the necessary management of acute renal failure—the elimination from intake of any dangerous substance that the kidney can no longer handle. The diet must either be free of protein or contain small amounts of high-quality protein to lessen tissue breakdown. It must also be free from sodium and potassium: many persons with renal failure have died from pulmonary edema, a correlate of sodium retention, and others from the acute toxic effects on the heart of a raised level of potassium in the blood. Water cannot be excluded from the intake but must be limited to an amount estimated to equal the unavoidable loss of water from the skin and in breathing. The weight of the patient and the concentration of sodium in the blood are good guides to the adequacy of water restriction. In the absence of continuing losses of sodium from the body, as might occur from vomiting or diarrhea, a progressive fall in serum sodium implies that too much water is being taken in. Kidney function may recover, often in seven to 10 days. The use of dialysis, the removal of waste products by straining the blood through semipermeable membranes, gives further time for renal recovery. Potassium can be removed from the body by resins, but this is less often required if dialysis is available.

Although by comparison with the oliguric phase the recovery phase presents fewer problems, the convalescent kidney takes time to recover its full regulatory function, and electrolytes and water may be lost at an unusual rate during this stage, requiring replacement. Most individuals who survive completely recover from acute renal failure, but residual renal damage persists in some persons. In a few, this is so severe as to bring them effectively into the category of chronic renal failure. The artificial kidney has transformed the outlook for many patients with acute renal failure, and this, together with developments in the control of infection with more powerful antibiotics, constitutes one of the miracles of medicine in the last few decades.

Chronic renal failure. The term uremia, though it is sometimes used as if it were interchangeable with chronic renal failure, really means an increase in the concentration of urea in the blood. This can arise in many acute illnesses in which the kidney is not primarily affected and also in the condition of acute renal failure described above. Uremia ought to represent a purely chemical statement, but it is sometimes used to denote a clinical picture, that of severe renal insufficiency.

Chronic renal failure: common causes

As with acute renal failure, there are many conditions that can lead to chronic renal failure. The two most common causes are pyelonephritis and glomerulonephritis (kidney inflammation involving the structures around the renal pelvis or the glomeruli), and other common causes are renal damage from the effects of high blood pressure and renal damage from obstructive conditions of the lower urinary tract. These primary disorders are described below. They have in common a progressive destruction of nephrons, which may be reduced to less than a 20th of their normal number. The quantitative loss of nephrons can account for the majority of the changes observed in chronic renal failure; the failure in excretion is due directly to loss of glomerular filters, and other features such as the large quantities of dilute urine represent a change in tubular function that could be accounted for by the increased load that each remaining nephron has to carry. There are many other causes of chronic renal failure aside from the four common ones. They include congenital anomalies and hereditary disorders; diseases of connective tissue; tuberculosis; the effects of diabetes and other metabolic disorders; and a number of primary disorders of the kidney tubules. Of the many causes, there are some that have importance out of proportion to their frequency, by virtue of their reversibility; these include renal amyloidosis (abnormal deposits in the kidney of a complex protein substance called amyloid), whose causes may be treatable; damage to the kidney from excessive calcium or deficiency of potassium; uric acid deposition in gout; the effects of analgesic agents (substances taken to alleviate pain) and other toxic substances, including drugs.

Effects of chronic renal failure

The person suffering from renal failure, especially in the early stages, may have no symptoms other than a feeling of thirst and a tendency (shared with many normal people) to pass urine at frequent intervals and through the night; or he may be in a coma, with occasional convulsions. The general appearance of the sufferer may be sallow because of a combination of anemia and the retention of urinary pigment. Even if not in actual coma, the affected person may be withdrawn; muscle twitchings and more general convulsions may occur. The coma is thought to represent poisoning, and convulsions are often related to the severity of the high blood pressure that commonly complicates advanced renal failure. Blurred vision is also a manifestation associated with high blood pressure. Bruising and hemorrhages may be noticeable.

Although the toxin (or toxins) of uremia has yet to be identified, the rapid improvement that follows dialysis points strongly to a toxic component. Urea itself is not notably toxic. Not all the chemical alterations in uremia are simple retentions. There is acidosis—a fall in the alkalinity of the blood and tissue fluids—reflected clinically in deep respiration as the lungs strive to eliminate carbon dioxide. The capacity of the kidney to adjust to variation in intake of salt, potassium, and water becomes progressively impaired, so that electrolyte disturbances are common. Poor appetite, nausea, vomiting, and diarrhea are common in uremic patients, and these in turn add another component to the chemical disturbance. Phosphate is retained ,in the blood and is thus associated with low blood levels of calcium; the parathyroids are overactive in renal failure, and vitamin D is less than normally effective because the kidneys manufacture less of its active form (1,25-dihydroxycholecalciferol). (Parathyroid hormone causes release of calcium from the bones, and vitamin D promotes absorption of calcium from the intestines.) These changes can lead to severe bone disease in persons suffering from renal failure, because bone calcium is depleted and the calcium stores are not adequately replenished.

In chronic renal failure, excessive production of renin by the kidney can lead to severe high blood pressure (hypertension), and the effects of this may even dominate the clinical picture. In addition to damage to the brain and the retina, the high blood pressure may lead directly to heart failure. Hypertension can also accelerate the progress of renal damage by its impact on the renal blood vessels themselves, setting up a cycle that can be hard to break. Anemia is also often severe due in part to a failure to produce erythropoietin.

The patient in advanced renal failure is vulnerable to infection and other complications, such as vomiting or diarrhea, which need special care. When symptoms of advanced renal failure appear, deterioration can be delayed by a strict low-protein diet, 18–20 grams of high-quality protein each day. In terminal renal failure, the affected person can be rescued only by some form of dialysis and then maintained by dialysis or transplantation.

Glomerulonephritis. Glomerulonephritis is the disorder commonly known as nephritis, or Bright's disease. The primary impact of the disease is on the vessels of the glomerular tuft. The suffix "-itis" suggests an inflammatory lesion, and glomerulonephritis is indeed associated with infection, in the limited sense that it may begin soon after a streptococcal infection and may be aggravated in its later course by infections of various kinds. Nevertheless, there is convincing evidence that glomerulonephritis does not represent a direct attack on the kidney by an infective agent; it appears to be, rather, an immunologic disorder, in the sense of the formation of antibodies in response to the presence of a foreign protein (antigen) elsewhere in the body; these form antigen–antibody complexes that lodge in the glomerular tuft or, in a small number of cases, themselves become deposited on the capillary glomerular walls. In each case the antibody or the antigen–antibody complex reaches the kidney via the circulation, and the mechanism is usually referred to as circulating complex disease. Glomerular damage is a consequence of the reaction that follows within the glomeruli. These deposits of foreign protein and complexes react with other protein components of blood (see the article COMPLEMENT in the *Micropædia*) and attract to the site white blood cells and platelets, which also are circulating in the blood; these in turn release protease enzymes and other chemical mediators of tissue injury.

Glomerulonephritis: allergic disorder

This view of glomerulonephritis is based partly on analogy with the renal damage that can be induced in animals by allergic mechanisms and partly on finding that a protein component of the allergic reaction is deposited in the diseased glomerulus. Within the general concept of an immunologic disorder, there is ample room for a variety of primary stimuli and of later immunologic disease-causing mechanisms. These include the possibility of primary glomerular damage, causing the glomerulus itself to become antigenic and so to provide a secondary antibody response, and also the participation of (or lack of participation of) T lymphocytes. Such a diversity is strongly suggested not only by the variations in the glomerular tissues observed both with the ordinary and with the electron microscope but also by the varying manifestations of the disease observed in the affected person.

Typically, glomerulonephritis appears as an acute illness one to two weeks after a sore throat, or—less commonly—after a persistent streptococcal infection of the skin. Other infective agents may be responsible, however, including some viruses and protozoans. A small number of drugs that act as foreign macromolecules can also do so.

The affected person has puffiness of the face and ankles and at the same time scanty and noticeably blood-stained urine. On examination, loose tissues show edema, and the fluid is easily displaced by light pressure; both the blood pressure and the blood levels of urea are slightly or moderately increased. The illness is an alarming one, but the fact is that the acute attack of glomerulonephritis needs no particular treatment other than the eradication of the infection or withdrawal of the offending drug, with some restriction of fluid and protein. Nine out of 10 affected persons recover completely. Exceptional outbreaks, with a higher mortality, have sometimes been observed. A very few patients may die in the acute attack, however, or in a few months' time, when the impact of the disease has been unusually severe. Another possibility is that the affected person may appear to have recovered completely, having lost all symptoms; but the disease process remains active, and there is progressive loss of nephrons, leading ultimately to chronic renal failure. This process may take many years, for most of which the person has no definite symptoms of latent nephritis except that the urine contains protein and small numbers of red blood cells. It need not be assumed, however, that the finding of protein in the urine (proteinuria) in the absence of symptoms means automatically that the patient has kidney disease; symptomless proteinuria has many causes and may indeed be found in young people who never develop any later evidence of renal disease.

In summary, glomerulonephritis can lead to renal failure within a few weeks or months, after many years of symptom-free proteinuria, or after a period of massive proteinuria, which causes the nephrotic syndrome. All of these manifestations may sometimes be seen in individuals who have never had, or cannot recall, an acute attack. Renal biopsies in many patients with glomerulonephritis show a range of glomerular reactions that include increased cellularity and basement membrane damage and thickening and varying degrees of progressive destruction of glomeruli. In those who recover, complete resolution of glomerular disease occurs.

A curious form of glomerulonephritis especially common in children is associated with little structural glomerular damage, at least as seen by the ordinary light microscope. Characteristic abnormalities affecting podocytes are revealed by electron microscopy. The condition is usually attended by heavy proteinuria and the nephrotic syndrome. Although the evidence for an immunologic cause of this form of glomerulonephritis is less certain than in other types, and the provoking antigen is unknown, paradoxically the disorder usually promptly resolves when the patient is treated with corticosteroids or other immunosuppressive drugs, and renal failure never occurs.

Vascular disease. In the discussion of chronic renal failure, attention was drawn to the cycle in which high blood pressure secondary to renal disease can produce further damage to the kidneys. Clearly, primary vascular disease—disease affecting the blood vessels—could equally well be a cause of renal damage.

The most dramatic instance of this is the condition known as malignant hypertension, or accelerated hypertension, which arises when the blood pressure attains extremely high levels, the diastolic figure (the blood pressure between heart contractions) being 140 millimetres of mercury or higher (the normal being around 80). Sustained levels of this magnitude cause serious damage to the arterioles, the smallest of the arteries; this damage is widespread, but as it affects the kidneys it produces rapid destruction of renal substance, with a scarred kidney. Unless the blood pressure is controlled, malignant hypertension can cause death in a few months; since treatment at an early stage is notably effective, the condition represents an important medical emergency. Since the retinas are damaged as rapidly as the kidneys, the affected person may first notice blurring or loss of vision.

More modest, but still elevated, levels of blood pressure can cause more gradual renal damage in elderly people or in those made prematurely aged by widespread arteriosclerosis ("hardening of the arteries"). In this condition the damage is in the larger arteries rather than in the arterioles, and the condition is one of slowly progressive scarring. Renal damage can also arise, by various mechanisms, in a large number of diseases that impair the proper functioning of the blood vessels, such as diabetes mellitus, the collagen disorders, bacterial inflammation of the heart lining, and many more.

A specific renovascular cause of high blood pressure that, although uncommon, is important from the point of view of the control of blood pressure in healthy individuals involves the juxtaglomerular apparatus (JGA) and the secretion of renin. Occasionally, following trauma or arising spontaneously as a result of vascular disease, one or the other of the main renal arteries becomes constricted (renal artery stenosis). The fall in blood pressure beyond the constriction leads to increased secretion of renin from the JGA with the formation of the vasoactive angiotensin II. As a result, the blood pressure rises. Removal of the affected kidney, surgical repair of the constriction, or percutaneous transluminal angioplasty (a balloon catheter inserted through the skin and inflated in the artery to flatten plaque build-up) usually restores the blood pressure and the blood renin level to normal.

Tumours. Tumours in general are covered in the article CANCER. In this section, those tumours peculiar to the excretory system, and their local effects, are discussed briefly. In the case of benign tumours, these effects include pressure on local structures and obstruction to hollow organs; with malignant tumours, one must add the possibilities of local invasion and of spread by the bloodstream or lymphatics to other organs (metastasis).

Carcinoma. The most common tumour of the renal substance is a carcinoma, renal cell cancer (formerly called a hypernephroma), which is a malignant tumour, arising from epithelial cells (the cells of the bodily coverings and linings). It was formerly thought to arise from adrenal cortical cells lying within the kidney substance. This has since been disproved. One to 2 percent of all tumours are renal carcinomas, and most affected persons are aged from 40 to 60. The tumour may be symptomless or may first be apparent from the occurrence of metastases in the lungs, causing spitting up of blood; or in the bones, causing pathological fracture.

Signs and symptoms of carcinoma

Much more commonly, the first evidence of the tumour is blood in the urine, which may be painless or may cause colic of the ureter, if clots are being passed. There may also be a dull pain in the loins, from stretching of the kidney capsule. The tumour may be directly palpable, or it may be revealed by X rays or ultrasonography. The silhouette of the kidney may be distorted by a rounded swelling; or the renal pelvis, made visible by the injection of a contrast medium, may be displaced or distorted. Less common first indications of renal carcinoma are an obscure fever, or polycythemia (excess of red blood cells in the blood), due to excessive production of erythropoietin. Direct visual examination of the urinary tract with an instrument called a cystoscope may demonstrate the side that is affected, blood coming from one ureteric opening only. Since this bleeding can equally arise from a tumour of the renal pelvis, examination of the renal pelvis is usually called for. An exploratory operation may sometimes be needed; if carcinoma is found to be present, the kidney must be removed. There is some evidence that the results of surgery may be somewhat improved by radiation therapy. The overall outlook is poor, with a five-year survival rate no better than 50 percent. This is, however, one of the forms of malignant tumour in which arrest or even regression has been described.

Nephroblastoma (Wilms' tumour). Nephroblastoma is a less common, but nevertheless an important, tumour in childhood, in which other forms of cancer are less common. About half the cases occur at ages two to four, but the tumour may be present even at birth. Early diagnosis, immediate surgery, and chemotherapy constitute the best possibility for a cure.

Other tumours. In addition to tumours of the renal substance, the renal pelvis may be affected by fernlike growths of the epithelium (papillomas). Benign tumours of the kidney substance occur, but rarely; on the other hand, cysts (abnormal sacs filled with liquid or semisolid substance) of the kidney are relatively common but are not tumours in any strict sense, being rather malformations brought about by failure of the embryonic tubules to achieve a proper outlet. Several forms of renal cystic disease, most of them fatal, occur in infancy. Various forms of solitary cyst occur, which may need local surgical treatment if they cause symptoms. The form of polycystic (multiple-cyst) renal disease that allows survival into adult life is a familial condition, in which several members of the family have little trouble until middle life but then are progressively affected by kidney malfunction. Episodes of blood in the urine and urinary infection are common, and the kidneys are large and irregular. Cysts of other organs—*e.g.*, the liver—may be present. X rays show irregularity of the renal pelvis, through pressure from the cysts. Puncture of the cysts is possible, but the results are not encouraging; the general treatment is that of chronic renal failure, which may now include removal of the kidney and transplantation.

OBSTRUCTION TO THE FLOW OF URINE

Effect of urinary obstruction on kidney

The causes of obstruction to the flow of urine lie in the lower urinary tract and are dealt with in a later section; here it is appropriate to consider the effects of urinary obstruction on the kidney (obstructive nephropathy). It should first be noted, however, that obstructions may arise at the junction of the renal pelvis and the ureter, either from faulty action of smooth muscle or from the pressure of an abnormal blood vessel crossing the pelvis; such cases can benefit from a plastic operation on the renal pelvis or from division of the abnormal vessel. Whether the obstruction arises in this way, or lower down, it can lead to renal pain, to the passage of irregular amounts of urine when obstruction is intermittent, and to a mass in the kidney when obstruction persists. As the renal pelvis swells, the renal tissue shrinks, leading to the condition called hydronephrosis, in which a greatly swollen sac is surrounded by a mere rind of atrophied renal tissue. A massive hydronephrosis, with negligible renal substance remaining, may suggest removal of the kidney.

Trauma

The kidney may be wounded, usually along with other viscera; it may be bruised; or it may even be ruptured in closed injuries. Since the kidney receives about a fifth of the blood pumped by the heart, bleeding can be profuse, both into the urine and into the tissues and the kidney, forming a large mass of blood, called a hematoma, and leading to surgical shock. Some bleeding may follow the procedure of renal biopsy (taking a specimen of kidney tissue for examination), but with proper precautions this is not severe. In the past, massive irradiation to the kidney region led to chronic renal damage (radiation nephritis), but with adequate precautions, this is no longer so.

The usual signs of traumatic injury to the kidney are blood in the urine and the development of a tender mass in the loin, with progressive signs of shock (pallor, sweating, fall in blood pressure). Such signs call for resuscitation and for surgical exploration if the bleeding continues. The surgical treatment may be carried out to arrest the bleeding by closing the tear. The kidney must be surgically removed if it cannot be saved. Abnormal solitary kidneys are not unknown, and such kidneys are more exposed to trauma by their size or position. Removal of such a kidney can lead only to death unless transplantation is possible.

SUBSTITUTING FOR RENAL FUNCTION

The failure of a vital function normally, and by definition, leads to death; but in the case of the kidneys there are two methods of substituting for renal function: transplantation and dialysis.

Transplantation. In principle the simpler of these two is to transplant a kidney from a donor, ideally an identical twin. The immunologic and surgical problems of transplantation are dealt with in the article TRANSPLANTS, ORGAN AND TISSUE. Here only the part played by renal transplantation in the total care of renal disease is considered. The question of a transplant does not arise in most cases of acute renal failure when the loss of function is largely recoverable; and in chronic renal failure it arises only when the residual renal function is barely adequate to support life.

Occasions for use of transplants and dialysis

Dialysis. Transplantation and dialysis are complementary rather than rival methods. Dialysis is used while a patient is awaiting transplant and during episodes of oliguria or of threatened rejection, while, on the other hand, patients who find dialysis a psychological burden can be offered a transplant. In addition to its complementary role in a transplant program, dialysis can be used independently in the maintenance of patients with chronic renal failure; and it can be used to preserve life in acute renal failure and in acute poisoning, to allow more time for recovery.

There are two main techniques of dialysis in current use. In peritoneal dialysis, the patient's own abdominal cavity is used as the container of fluid; the fluid is run in, allowed to reach equilibrium, and removed, taking with it urea and other wastes. The process has proved suitable for the short-term treatment of acute renal failure, especially in infants, and can be used in the treatment of individuals with chronic irreversible renal failure. New techniques have allowed many patients to conduct peritoneal dialysis on their own for limited periods of time.

Hemodialysis (filtration of the blood through semipermeable membranes) has also been used in the treatment of acute renal failure, since the method—the artificial kidney—was devised, in the 1940s; but, for chronic use, the problem was one of repeated access to the arterial bloodstream. This was largely solved by the introduction of a permanent shunt between an artery and a vein (an arteriovenous fistula), by which a suitable vein, usually in the arm, is connected directly to an adjacent artery. The vein becomes distended and so can be repeatedly punctured to gain access to blood, which can then be diverted through the "artificial kidney" when required. In the original artificial kidney, the patient's blood was pumped through cellophane tubing immersed in a large bath of physiological fluid (solution of the same osmotic pressure as blood); in some later models, streams of blood and of dialyzing fluid are made to flow in opposite directions, separated by plastic sheets. This introduction of the "countercurrent" principle has allowed the apparatus to be smaller, and disposable versions of both patterns are now available. Some patients on intermittent hemodialysis have been kept alive for nearly 20 years. Most continued hemodialysis is still done in hospitals or special centres; but some patients using automatic equipment have been successfully trained to carry out the procedure in their own home.

DISEASES AND DISORDERS OF THE URINARY TRACT

Obstruction. While it is possible for the urinary tract to be obstructed by a large mass (tumour, stone, or foreign body) lying in the bladder, the tubular portions of the tract (urethra and ureters) are much more vulnerable to obstruction. The urethra may be obstructed by stones (calculi) formed in the bladder or kidneys; by fibrous contraction of the urethral wall (urethral stricture); and by congenital valve or diaphragm (membranous malformation). Although not a part of the excretory tract, the prostate lies close to the bladder neck, and in older men it is an important cause of obstruction; fibrous disease of the bladder neck can also cause obstruction. The ureters can likewise be obstructed by calculi and stricture (narrowing); by fibrosis—scarring—of surrounding tissue (retroperitoneal fibrosis); and by tumour, though this is more likely to cause blood in the urine (hematuria).

Characteristics of urinary calculi

Urinary calculi vary greatly in size. Mostly they contain calcium phosphate, calcium oxalate, uric acid, or cystine. Predisposing factors include infection, a high rate of calcium excretion, a low rate of urine formation, and various metabolic disorders, notably gout. They may cause trouble by their size or by entering the ureter or urethra, giving rise to colic, to hematuria, and, in the event of impaction, to obstructive kidney disease. The direct treatment of calculi is surgical, but sometimes the stone can be fragmented in situ by a lithotriptor. The sufferer needs general investigation for any underlying cause (*e.g.,* a functioning parathyroid tumour that causes excessive excretion of calcium).

In the past at least, a common cause of urethral stricture was gonorrhea, in which inflammation of the urethra is followed by scarring and stricture. Bruising of the urethra by instruments during treatment can also occur. The affected person has increasing difficulty in passing urine, and the bladder becomes distended. Treatment may be either by repeated dilation of the stricture or by surgery.

Trauma. Apart from the urethra, the urinary tract is likely to be injured only in massive general injury or by accidental ligation (tying) of the ureters in a pelvic operation. The urethra can, however, be ruptured by a blow or fall on the perineum (crotch). If there is no external wound, the damage is indicated by the appearance of a swelling containing blood and urine, by the inability to pass urine, and by bleeding from the urethra. The patient becomes shocked and urgently needs surgical repair of the urethra and drainage of the potentially infected swelling.

Tumour. The occurrence of papillomatous tumours of the renal pelvis has already been mentioned. Similar tumours in the lower urinary tract give rise to painless hematuria. Workers with the chemicals naphthylamine and benzidine have a high incidence of bladder tumours, often multiple and recurrent. Blood in the urine is the most frequent symptom, but bladder irritation with difficulty in urination appears later. Removal when practicable or destruction by diathermy are normal treatments.

Situations leading to urinary infection

Infection of urinary tract. Infection of the urinary tract is a common and important cause of both minor and major illness. At one extreme, an attack of cystitis—inflammation of the bladder—may cause only trivial discomfort; on the other hand, infection once established may cause lifelong discomfort, may be largely unresponsive to treatment, and may greatly shorten life itself. Infection may be with a great variety of organisms, but the most common are those that normally inhabit the bowel, where they are relatively harmless, becoming a cause of disease only when they enter vulnerable tissue. Because of the short female urethra, urinary infections are more common in women than in men and occur especially during pregnancies, when there may be partial stagnation of the urine from pressure on the urinary tract. In later life, as prostatic disease becomes more common, urinary infection becomes more of a problem in men. Another vulnerable period is infancy, when the use of diapers probably facilitates entry of organisms into the urethra. The introduction of a catheter into the bladder may be necessary to relieve urethral obstruction, but since the procedure always carries a risk of introducing infection, it is not lightly undertaken.

In all forms of urinary infection the urine may be cloudy and may contain more ammonia than usual. Urination tends to be painful if the urethra is inflamed, and both painful and frequent if inflammation involves the bladder. Bladder infection may also cause fever, dull pain in the lower part of the abdomen, and vomiting. If the infection reaches the kidneys, symptoms are even more severe, and there is pain in the loins, on one or both sides, and sometimes high fever.

Urinary infection may generally be diagnosed from the symptoms and from laboratory examination of the urine. The treatment is usually the administration of sulfonamides or broad-spectrum antibiotics. The extent to which repeated, or recurrent, urinary tract infection may lead to chronic pyelonephritis (inflammation of the kidney and lining of the renal pelvis) and renal failure remains a controversial issue. It is agreed that, in the presence of obstruction to the flow of urine, urinary infection is prone to ascend the urinary tract and cause intractable infection within the renal pelvis and kidney tissue. Infection can rarely be eradicated by antibiotics until the obstruction is removed or relieved. Although many patients have signs of progressive renal damage they have sterile urine and no signs of infection. Investigations, including direct histological examination of the kidneys, however, reveal that chronic inflammation has been present for many years within and between the renal tubules (interstitial nephritis). Some of these patients admit to excessive and prolonged use of nonsteroidal analgesic drugs such as phenacetin. In others it is possible that urinary tract infection and renal damage began in infancy, possibly encouraged by regurgitation of urine into the ureter and pelvis as a result of an incompetent ureterovesical valve (vesicoureteric reflux). This process not only damages the kidneys directly at an early age but favours the development of infection and leads in later life to the development of kidneys distorted by fibrosis and scar tissue. In any event, pyelonephritis and glomerulonephritis are by far the two most common causes of chronic renal failure sufficiently severe to necessitate dialysis or renal transplantation.

Like other tissues, the excretory system can be involved in tuberculous infection. This is now relatively uncommon and, when it occurs, can often be managed by the general chemotherapy appropriate to tuberculous infection. Advanced renal tuberculosis requiring removal of the kidney rarely occurs. (D.A.K.B./J.S.Ro.)

RENAL DISORDERS IN PREGNANCY

The pregnant woman is especially vulnerable to two renal disorders: acute urinary tract infection and preeclampsia. Acute urinary tract infection, as discussed above, is the most common complication of pregnancy; although it is responsible for much discomfort and distress, it does not affect mortality of either mother or fetus.

While elevation of blood pressure may accompany the onset of pregnancy, the development of rising levels of blood pressure in the last three months of pregnancy is particularly ominous and heralds the onset of a condition known as preeclampsia; this is especially prone to occur in a first pregnancy. In addition to high blood pressure, there is rapid weight gain, fluid retention, and proteinuria. The condition has been described as a "disease of theories," because its cause remains obscure. Its development, however, is certainly linked to the presence of the placenta and fetus within the uterus (womb). It seems likely that an initiating event is insufficient blood flow to the uterus, which in turn leads to ischemia of the placenta; *i.e.*, parts of the placental tissue undergo degeneration or die. This in turn releases substances into the bloodstream that increase the tendency for the blood to clot within renal capillaries and small blood vessels elsewhere in the body. Renal failure and other organ damage then ensues, and hypertension becomes more severe. If the condition is untreated, generalized seizures and convulsions follow (eclampsia). Eclampsia is a serious condition with high fetal and maternal death. It does not develop if preeclampsia is treated sufficiently early. Hypertension must be controlled through drug therapy, and it is desirable that the baby be delivered some weeks before full term. (J.S.Ro.)

Exercise and Physical Conditioning

The terms exercise and physical activity are often used interchangeably, but this article will distinguish between them. Physical activity is an inclusive term that refers to any expenditure of energy brought about by bodily movement via the skeletal muscles; as such, it includes the complete spectrum of activity from very low resting levels to maximal exertion. Exercise is a component of physical activity. The distinguishing characteristic of exercise is that it is a structured activity specifically planned to develop and maintain physical fitness. Physical conditioning refers to the development of physical fitness through the adaptation of the body and its various systems to an exercise program.

This article is divided into the following sections:

A HISTORICAL VIEW OF EXERCISE

Prehistoric period. Hominids—human beings and their immediate ancestors—have existed on Earth for at least 2,000,000 years. For more than 99 percent of that time, hominids lived a nomadic existence and survived by hunting and gathering food. It is obvious that this way of life was enormously different from the way people live today in developed countries. Thus, evolutionary history has prepared humankind for one kind of life, but modern people lead another. This fact has profound implications for patterns of disease and for the association between living habits and health. Observation of the few remaining nomadic groups in the world indicates that they are relatively free of chronic diseases and that, in comparison to the populations in developed countries, they are leaner, have a higher level of physical fitness, eat a very different diet, and have different physical activity patterns. Data from the distant past are not available, but it is reasonable to speculate that early humans had considerably higher caloric expenditures per unit of body weight than do modern individuals.

Agricultural period. As civilization developed, nomadic hunting and gathering societies gave way to agricultural ones in which people grew their own food and domesticated animals. This development occurred relatively recently, approximately 10,000 years ago. Although many aspects of life changed during the agricultural period, it is likely that energy demands remained high, with much of the work still done by human power. Even in cities—which had evolved by about midway through the agricultural period—individuals expended more calories than do most people today.

Industrial period. The industrial period began during the mid-18th century, with the development of an efficient steam engine, and lasted to the end of World War II (1945). This relatively brief time span was characterized by a major shift in population from farms to cities, with attendant changes in many areas of life-style. Even though the internal-combustion engine and electrical power were increasingly used to perform work, the great majority of individuals in industrialized societies still faced significant energy demands. In the cities relatively more individuals walked to work, climbed stairs, and had more physically demanding jobs than do most people today.

Effects of labour-saving devices

Technological period. The post-World-War-II period has been a technological age, a period characterized by rapid growth in energy-saving devices, both in the home and at the workplace. As an example, longshoremen in the late 1940s worked hard loading and unloading ships; by contrast, most longshoremen in the late 20th century had much lower energy demands from the job, because of the containerization of cargo and the mechanization of the loading and unloading process. Also during this period, the use of labour-saving devices in the home and in yard and garden work became much more widespread. Physical activity became less and less common in industrialized countries, especially among the urban population. Although the level of general physical activity has declined, most observers feel that there have been increases in exercise participation in many countries since the late 1960s. Jogging, racket sports, cycling, and other active recreational pursuits have become much more common. In a sense this is simply humankind's returning to the more active life-style of its distant ancestors.

TYPES OF PHYSICAL FITNESS

Physical fitness is a general concept and is defined in many ways by different scientists. Physical fitness is discussed here in two major categories: health-related physical fitness and motor-performance physical fitness. Despite some overlap between these classifications, there are major differences, as described below.

Health-related physical fitness. Health-related physical fitness is defined as fitness related to some aspect of health. This type of physical fitness is primarily influenced by an individual's exercise habits; thus, it is a dynamic state and may change. Physical characteristics that constitute health-related physical fitness include strength and endurance of skeletal muscles, joint flexibility, body composition, and cardiorespiratory endurance. All these attributes change in response to appropriate physical conditioning programs, and all are related to health.

Strength and endurance of skeletal muscles of the trunk help maintain correct posture and prevent such problems as low back pain. Minimal levels of muscular strength and endurance are needed for routine tasks of living, such as carrying bags of groceries or picking up a young child. Individuals with very low levels of muscular strength and endurance are limited in the performance of routine tasks and have to lead a restricted life. Such limitations are perhaps only indirectly related to health, but individuals who cannot pick up and hug a grandchild or must struggle to get up from a soft chair surely have a lower quality of life than that enjoyed by their fitter peers.

Flexibility, or range of motion around the joints, also ranks as an important component of health-related fitness. Lack of flexibility in the lower back and posterior thigh is thought to contribute to low back pain. Extreme lack of flexibility also has a deleterious effect on the quality of life by limiting performance.

Body composition refers to the ratio between fat and lean tissue in the body. Excess body fat is clearly related to several health problems, including cardiovascular disease, type II (adult-onset) diabetes mellitus, and certain forms of cancer. Body composition is affected by diet, but exercise habits play a crucial role in preventing obesity and maintaining acceptable levels of body fat.

Cardiorespiratory endurance, or aerobic fitness, is probably what most people identify as physical fitness. Aerobic fitness refers to the integrated functional capacity of the heart, lungs, vascular system, and skeletal muscles to expend energy. The basic activity that underlies this type of fitness is aerobic metabolism in the muscle cell, a process in which oxygen is combined with a fuel source (fats or carbohydrates) to release energy and produce carbon dioxide and water. The energy is used by the muscle to contract, thereby exerting force that can be used for movement. For the aerobic reaction to take place, the cardiorespiratory system (*i.e.*, the circulatory and pulmonary systems) must constantly supply oxygen and fuel to the muscle cell and remove carbon dioxide from it. The maximal rate at which aerobic metabolism can occur is thus determined by the functional capacity of the cardiorespiratory system and is measured in the laboratory as maximal oxygen intake. As will be discussed in detail below, aerobic fitness is inversely related to the incidence of coronary heart disease and hypertension.

Motor-performance physical fitness. Motor-performance fitness is defined as the ability of the neuromuscular system to perform specific tasks. Test items used to assess motor-performance fitness include chin-ups, sit-ups, the 50-yard dash, the standing long jump, and the shuttle run (a timed run in which the participant dashes back and forth between two points). The primary physical characteristics measured by these tests are the strength and endurance of the skeletal muscles and the speed or power of the legs. These traits are important for success in many types of athletics. Muscular strength and endurance are also related to some aspects of health, as stated above.

There is disagreement among experts about the relative importance of health-related and motor-performance physical fitness. While both types of fitness are obviously desirable, their relative values should be determined by an individual's personal fitness objectives. If success in athletic events is of primary importance, motor-performance fitness should be emphasized. If concern about health is paramount, health-related fitness should be the focus. Different types of fitness may be important not only to different individuals but also to the same individual at different times. The 16-year-old competing on a school athletic team is likely to focus on motor performance. The typical middle-aged individual is not as likely to be concerned about athletic success, emphasizing instead health and appearance. One further point should be made: to a great extent, motor-performance physical fitness is determined by genetic potential. The person who can run fast at 10 years of age will be fast at age 17; although training may enhance racing performance, it will not appreciably change the individual's genetically determined running speed. On the other hand, characteristics of health-related physical fitness, while also partly determined by inheritance, are much more profoundly influenced by exercise habits.

The role of
heredity

PRINCIPLES OF EXERCISE TRAINING

Research in exercise training has led to the recognition of a number of general principles of conditioning. These principles must be applied to the development of a successful exercise program.

Specificity. The principle of specificity derives from the observation that the adaptation of the body or change in physical fitness is specific to the type of training undertaken. Quite simply this means that if a fitness objective is to increase flexibility, then flexibility training must be used. If one desires to develop strength, resistance or strengthening exercises must be employed. This principle is indeed simple; however, it is frequently ignored. Many fraudulent claims for an exercise product or system promise overall physical fitness from one simple training technique. A person should be suspicious of such claims and should consider whether or not the exercise training recommended is the type that will produce the specific changes desired.

Overload. Overload, the second important principle, means that to improve any aspect of physical fitness the individual must continually increase the demands placed on the appropriate body systems. For example, to develop strength, progressively heavier objects must be lifted. Overload in running programs is achieved by running longer distances or by increasing the speed.

Progression. Individuals frequently make the mistake of attempting too rapid a fitness change. A classic example is that of the middle-aged man or woman who has done no exercise for 20 years and suddenly begins a vigorous training program. The result of such activity is frequently an injury or, at the least, stiffness and soreness. There are no hard-and-fast rules on how rapidly one should progress to a higher level of activity. The individual's subjective impression of whether or not the body seems to be able to tolerate increased training serves as a good guide. In general it might be reasonable not to progress to higher levels of activity more often than every one or two weeks.

Warm-up/cool down. Another important practice to follow in an exercise program is to gradually start the exercise session and gradually taper off at the end. The warm-up allows various body systems to adjust to increased metabolic demands. The heart rate increases, blood flow increases, and muscle temperatures rise. Warming up is certainly a more comfortable way to begin an exercise session and is probably safer. Progressively more vigorous exercises or a gradual increase in walking speed are good ways to warm up. It is equally important to cool down—that is, to gradually reduce exercise intensity—at the end of each session. The abrupt cessation of vigorous exercise may cause blood to pool in the legs, which can cause fainting or, more seriously, can sometimes precipitate cardiac complications. Slow walking and stretching for five minutes at the end of an exercise session is therefore a good practice. The heart rate should gradually decline during the cool down, and by the end of the five minutes it should be less than 120 beats per minute for individuals under 50 years of age and less than 100 beats per minute for those over 50.

Frequency, intensity, and duration. To provide guidance on how much exercise an individual should do, exercise physiologists have developed equations based on research. It is generally agreed that to develop and maintain physical fitness, the exercise must be performed on a regular basis. A frequency of about every other day or three days per week appears minimally sufficient. Many individuals exercise more frequently than this, and, of course, such additional exercise is acceptable provided that one does not become overtrained and suffer illness or injury.

The intensity of exercise required to produce benefits has been the subject of much study. Many people have the impression that exercise is not doing any good unless it hurts. This is simply not true. Regular exercise at 45 to 50 percent of one's maximal capacity is adequate to improve one's physiological functioning and overall health. This level of intensity is generally comfortable for most individuals. A reliable way to gauge exercise intensity is to measure the heart rate during exercise. An exercise heart rate that is 65 percent of a person's maximal heart rate corresponds to approximately 50 percent of his maximal capacity. Maximal heart rate can be estimated by subtracting one's age in years from 220 (or, in the case of active males, by subtracting half of one's age from 205). Thus, a sedentary 40-year-old man has an estimated maximal heart rate of 180 beats per minute. Sixty-five percent of this maximal rate is 117 beats per minute; thus by exercising at 117 beats per minute, this individual is working at about 50 percent of his maximal capacity. To determine exercising heart rate, a person should exercise for several minutes, to allow the heart rate to adjust. The exerciser should then stop exercising, quickly find the pulse, and count the number of beats for 15 seconds. Multiplying this by four gives the rate in beats per minute. The pulse

Heart rate
as a gauge
of exercise
intensity

must be taken immediately after stopping exercise, since the heart rate rapidly begins to return to the resting level after work has been stopped. As noted above, exercising at the 50 percent level of intensity will improve physiologic functioning and provide health benefits. This level of exercise will not produce the maximum fitness needed for competitive athletics.

There is a relationship between the recommended duration of exercise and the intensity of exercise. If one exercises at a very high intensity, the duration of the exercise need not be as long to produce physiological changes. At lower intensities, duration must increase. The table presents guidelines for reasonable intensity, duration, and frequency.

Guidelines for Intensity, Duration, and Frequency of Exercise

exercise heart rate (beats/minute)	duration of session (minutes)	sessions per week
140	20	4
130	30	3
120	45	5

These values apply to a 40-year-old person.

Overall conditioning. Much emphasis has been given in the foregoing discussion to aerobic fitness, because this form of conditioning is extremely important. It should be noted, however, that other types of conditioning also have benefits. A total exercise program should include strengthening exercises, to maintain body mass and appropriate levels of strength for daily functioning, and stretching exercises to maintain joint mobility and flexibility. The specificity principle described above indicates that no one exercise is likely to produce the overall conditioning effect. In general an exercise plan should consist of aerobics, exercises that increase the strength and endurance of various skeletal muscle groups, and flexibility exercises to maintain good joint function.

Individual differences. The principles of exercise training discussed above should be viewed as general guidelines. Individuals differ in both physiological and psychological adaptations to exercise. Two people who are similar in many respects and who start the same exercise program may have entirely different impressions of it. One person may feel that the exercise is too easy, while the other may believe that it is much too hard. It is certainly appropriate that the exercise plan be adjusted to account for preferences. Likewise some individuals will progress to more intense training levels far more rapidly than others do. As mentioned earlier, exercise progress should be adjusted according to the exerciser's own assessment.

Individuals also differ in the type of exercise they like or can tolerate. Jogging, for instance, is not for everyone. Many people who dislike jogging, or who suffer running injuries, can find other satisfactory exercise activities, such as cycling, walking, swimming, or participating in a sport. Many kinds of exercise activities are appropriate and can provide physiological and health benefits to the participant. There is no one best exercise. The important thing is to be regular in exercise participation and to follow the general guidelines outlined in this section.

PHYSIOLOGICAL EFFECTS OF EXERCISE

Strength training

Neuromuscular effects. *Strength and endurance.* Appropriate exercise increases the strength and endurance of skeletal muscles. Increases in muscular strength are associated with increases in muscle mass; increases in muscular endurance are associated with improved blood flow to the working muscles. These results are achieved by resistance training. Any exercise that causes the muscle to increase its tension, whether or not the muscle actually shortens during contraction, provides an appropriate strength-training stimulus. Resistance can be applied to a muscle group by attempting to move an immovable object, by working one muscle group against another, by lifting heavy weights, or by using special strength-training machines and devices. There is a wide selection of strength-training equipment that, when used properly, can increase muscular strength and endurance. It is possible that some of the equipment is more efficient in developing maximal performance, which is important for competitive athletes. But for the average individual, who is training to maintain an acceptable level of muscular fitness, any one device or program is probably about as good as another.

Strength and endurance training is done by performing several "reps" (repetitions) of a given exercise, then moving on to another exercise for a different muscle group. Experts generally recommend that exercisers select a resistance that is approximately 65 percent of the maximum they can lift for that particular exercise. This load should allow the completion of 12 reps of that exercise in 24 to 30 seconds. Each group of eight to 12 reps is called a set, and two or three sets of a given exercise are recommended for each training session. The average individual should perform strength and endurance training two to three days per week. Super circuit weight training refers to a program in which running or other aerobic exercises are performed between sets; this training produces aerobic as well as strength benefits.

Stretching technique

Flexibility. Muscles and tendons can be stretched to improve flexibility (the range of motion at a joint). Flexibility training follows a few, simple principles. To improve range of motion, the muscles and other connective tissue around a joint must be stretched. The preferred stretching technique is a slow increase in the range of motion. The exerciser should feel the muscle stretch, but not to the point of pain. The stretch should be performed gradually, and the body should be held for 10 to 20 seconds in the stretched position and then gradually returned to a relaxed posture. By stretching each muscle group in this fashion as a part of the strengthening and conditioning program, the participant will maintain good flexibility. Bouncing or explosive stretching movements should be avoided, as they can result in muscle or tendon tears.

Cardiorespiratory effects. *Cardiac effects.* Regular aerobic exercise training has a direct effect on the heart muscle. The muscle mass of the left ventricle, which is the pumping chamber that circulates blood throughout the body, increases with exercise training. This change means that the heart can pump more blood with each beat. In short, the heart becomes a bigger, stronger, and more efficient pump capable of doing more work with less effort.

Circulatory effects. Regular exercise also produces changes in the circulation. As previously discussed, muscle endurance training serves to increase blood flow to the working muscles. This increased blood flow means that more oxygen and fuel can be delivered to the muscle cells. The number of red blood cells, which carry oxygen in the blood, also increases with training, as does blood volume. Taken together, these changes indicate a greater capacity to transport oxygen to the working muscles.

Pulmonary effects. The basic function of the lungs is to facilitate the transfer (1) of oxygen from the atmosphere into the blood and (2) of carbon dioxide from the blood into the atmosphere. To accomplish this, air must pass into and out of the lungs, and the respiratory gases must diffuse through the lungs into the circulation and vice versa. Although exercise has not been shown to affect this diffusing ability, exercise training does strengthen the muscles of respiration. This means that a trained individual can move more air through the lungs per time unit, and forced vital capacity (*i.e.*, the maximum volume of air that can be exhaled after a full inspiration) may be increased.

HEALTH EFFECTS OF EXERCISE

Effects on energy-spending ability

Improved general fitness. The greatest benefit of a regular exercise program is an improvement in overall fitness. As discussed above, appropriate exercise improves muscular strength and endurance, body composition, flexibility, and cardiorespiratory endurance. The level of maximal oxygen intake or cardiorespiratory endurance is not by itself of great importance to most individuals. What is important is that one's sustained energy-spending ability is directly related to maximal levels of performance. For example, consider the simple task of walking at a rate of three miles per hour. This task involves an energy expenditure of approximately three times the resting metabolic rate. Extremely unfit individuals may have a maximal aerobic power of only six times their resting metabolic rate. For such individuals, a three-mile-per-hour walk requires half of their maximal capacity. A middle-aged person who exercises regularly will have a maximal aerobic power 10 to 12 times resting, so the same walk will represent only 25 to 30 percent of maximal capacity. This example illustrates how any submaximal task is relatively much easier for the conditioned individual. Moreover, a person cannot work throughout the day at much more than about 20 percent of maximal capacity without becoming chronically fatigued. The deconditioned person who has a maximal aerobic power of six times resting can comfortably sustain a work level of only about 1.2 times resting throughout the day (6 × 0.20 = 1.2). This low capability for sustained energy expenditure can support only a very sedentary existence: for example, 20 hours of sleep and rest, two hours of personal care, one hour of housework and shopping, and one hour of activity at three times the resting rate each day.

The point of the preceding discussion is that the average energy-expenditure requirement of anyone's life can be calculated, and a person's maximal cardiorespiratory endurance determines how active a life-style can be sustained. Individuals who attempt to lead more active lives than their fitness level will support become chronically fatigued. Persons with adequate or optimal fitness levels, on the other hand, are able to meet the physical demands of an active life relatively easily. One of the most frequent observations made by individuals who have begun an exercise program is that they feel better, and research studies document an improvement in feelings of general well-being in more active people.

Decreased risk of coronary heart disease. Coronary heart disease is the leading cause of death in the developed world. Coronary heart disease is defined as myocardial infarction, or heart attack; angina pectoris, or chest pain; or sudden death due to cardiac arrest or abnormal electrical activity in the heart. The basic disease process that underlies coronary heart disease is atherosclerosis, a disorder characterized by the accumulation of cholesterol and the proliferation of smooth muscle cells in the linings of the arteries. This results in a gradual narrowing of the arterial channel, and this narrowing diminishes and may ultimately stop blood flow through an artery. When this occurs in a coronary artery—that is, an artery supplying the heart—one of the manifestations of coronary heart disease occurs.

Atherosclerosis

Epidemiological evidence of exercise benefits. Studies have linked sedentary living with high rates of coronary heart disease mortality. One study found that San Francisco longshoremen who worked in jobs requiring high levels of energy expenditure had less risk of dying of heart disease than did longshoremen who performed sedentary jobs. This study showed that dockworkers and cargo handlers expended at least 1,000 kilocalories more per day than did clerks and foremen and that sedentary workers, during a 22-year observation, were about twice as likely to die from heart disease. The higher risk of death in the less active men was not due to other coronary heart disease risk factors, such as smoking, obesity, and high blood pressure; nor was it the result of less healthy men's shifting to sedentary jobs.

Another study followed the health status of approximately 17,000 male graduates of Harvard University for many years. All these men essentially had sedentary jobs, but they differed in the amount of leisure time they spent on physical activities. Men who expended at least 2,000 kilocalories per week on physical activity had only half the death rate from heart disease as did those men who expended less than 500 kilocalories per week. Not all of this energy was spent in exercise programs; some was expended during routine activities such as climbing stairs.

The effect of exercise on coronary-heart-disease risk factors. One of the important medical achievements of the 20th century has been the development of the risk-factor theory of coronary heart disease. Scientists have discovered that persons who are overweight, smoke cigarettes, have high blood pressure, or show elevated blood levels of certain types of fat- and cholesterol-carrying molecules are much likelier to die from coronary heart disease. Furthermore, combinations of these risk factors result in exponential increases in the risk of death. The discovery and description of risk factors have led to an understanding of the atherosclerotic process and of how to prevent and treat it. Evidence suggests that regular exercise can lower a person's exposure to several of the risk factors.

Fat and cholesterol are transported by the blood in complex molecules called lipoproteins. Researchers have identified several classes of lipoproteins and have elucidated their roles in atherosclerotic progression. It is, therefore, possible to describe abnormal, or high-risk, lipoprotein profiles. Diet and heredity are key factors determining a person's lipoprotein profile, and exercise also plays an important role. Regular aerobic exercise improves the lipoprotein profile in most individuals. Although more work is needed to completely understand this association, the dose of exercise necessary to effect a beneficial change in the lipoprotein profile seems to be about eight to 10 miles of running (or its equivalent in other activity) per week.

Elevated blood pressure (hypertension) is a second powerful risk factor for coronary heart disease. Sedentary living habits and low levels of physical fitness increase the risk of developing hypertension. Exercise also appears to lower blood pressure in at least some individuals with hypertension. The greatest benefit is probably for younger people (those less than 40 to 45 years of age) whose hypertension is of relatively recent onset.

Effect of exercise on high blood pressure

Excess body weight is considered by most experts to be an independent risk factor for coronary heart disease, although obesity also indirectly increases the risk via deleterious impact on blood pressure and the lipoprotein profile. Exercise habits are strongly related to body weight. In virtually all studies of large populations, the more active individuals weigh less. One of the most consistent results seen in exercise-training studies is the loss of body weight and fat. Weight-loss programs that incorporate exercise as well as diet are more successful than those that rely on diet alone.

Impact on other chronic diseases. Although more research is needed to arrive at definitive conclusions, some evidence has suggested that regular exercise may help in the treatment or prevention of other chronic diseases. The control of type II diabetes, for example, appears to be aided by regular exercise. This form of diabetes is a major health problem in which the patient shows elevated levels of blood sugar despite having acceptable levels of insulin, the hormone that normally clears the blood of excess sugar by facilitating its utilization by the body cells. Persons with this disease need to control their blood sugar, but not with insulin injections. Oral medications that lower blood-sugar levels are available, but their usefulness has been questioned. Consequently, dietary modifications and exercise, both of which can lower blood-sugar levels, have become the key measures in controlling type II diabetes. Exercise seems to improve the insulin sensitivity of cells, so that blood sugar can more readily be taken in and used as fuel.

Effect of exercise on diabetes

A few reports have linked low physical activity with a higher risk of developing certain cancers, particularly colon cancer. These results are intriguing, but more work is needed to firmly establish that sedentary habits are an independent risk factor for cancer.

RISKS OF EXERCISE

As can be seen from the foregoing discussion, regular participation in an exercise program can provide several benefits. Yet exercise is similar to other medical or health interventions in that there are also potential costs associated with the activity. These costs range from minor inconveniences, such as time taken up by exercise, to more serious complications, including injury and even sudden death.

Injuries. It is clear that some people who participate in exercise training will develop injuries to their bones, muscles, and joints. Despite unfounded reports in the mass media of extremely high injury rates among adult exercisers, there have been few good studies of exercise injuries in populations. One of the difficulties in performing such studies has been the need to identify both the number of cases (individuals who become injured) and the number of persons at risk for injury (the total number of individuals exercising in the population). These two figures are necessary in order to calculate true injury rates. The best available studies on injury rates suggest that about 25 to 30 percent of adult runners will become injured over the course of a year, if injury is defined as an incident that causes an individual to stop exercising for at least one week. If only more serious injuries, such as those for which the individual seeks medical care, are considered, injury rates are much lower, perhaps in the range of 1 percent per year.

Little is known about the causes of exercise injuries. One factor that has been linked to injury is the amount of exercise; for example, individuals who run more miles are likelier to be injured than those who run fewer miles. Factors such as age, sex, body type, and experience have not been shown to be associated with risk of injury. It seems logical that structural abnormalities, sudden increases in training intensity, and types of equipment used are likely to be related to injury risk; however, data to support these opinions are not available.

How to avoid injuries

In view of the limited scientific data on injury risk, the exerciser is advised to follow commonsense practices until such time as the causes of injury are better understood. Exercisers should start their program slowly and gradually progress to more intensive training levels. They should use good equipment and pay particular attention to proper footwear. Exercisers who have had previous injuries should recognize that they may be more susceptible to similar injuries in the future. All exercisers should use caution and should monitor their bodies for the early warning signs of injury. If a problem begins to develop, it is good advice to stop exercising or to reduce the intensity of training for a few days to see if the problem disappears. Exercisers should not be afraid to experiment on themselves to find out what training practices and techniques seem to be more comfortable and less likely to produce injury. Moderation is good advice: few injuries are reported in individuals who run 10 to 15 miles per week, and this level is adequate to provide many health benefits.

Sudden death. Obviously, the most serious complication from an exercise program is sudden death. This is, fortunately, a rare occurrence. As discussed earlier, several studies have shown that individuals who regularly participate in exercise have a lower risk of dying from a heart attack. There is, however, also evidence that suggests a higher risk of dying during exercise than during sedentary activities. When one considers the total risk of sudden death over a 24-hour period, regular exercisers are much less likely to experience this catastrophe.

Virtually all individuals who drop dead suddenly have advanced coronary heart disease. It follows, therefore, that the best way to reduce the risk of sudden death during exercise is to avoid getting advanced coronary heart disease. This implies following good health practices in other aspects of life, such as not smoking, eating a prudent diet, and maintaining an ideal body weight. Individuals who are middle-aged or older can probably reduce their risk of sudden death by knowing about their coronary risk status and their general state of health before undertaking an exercise program. There are, of course, no guarantees, but if an individual has a thorough examination by a competent physician, including a maximal exercise test and other procedures that screen for coronary heart disease, that person can probably safely begin an exercise program.

SUMMARY

There has been much progress in the field of exercise and physical conditioning. Concepts about exercise have moved from faddism to scientific legitimacy, thanks to researchers in physical education, exercise physiology, and medicine. Yet much remains to be learned, and experts need to work together to further develop the study and promotion of exercise. There are many items that need further study, from the cellular level to the population as a whole. For example, more information is needed on specifically how exercise affects blood lipoprotein levels, and further research is needed on rates of injuries in populations of exercisers.

Exploration

Of all the characteristics that human beings have used to distinguish themselves from "lower" animals, the desire to explore the unknown may be the most enduring. As the Norwegian polar explorer and oceanographer Fridtjof Nansen observed, "Man wants to know, and when he ceases to do so, he is no longer man."

The gradual expansion by certain animals into new ranges cannot be regarded as exploration. Rather, such movements are merely shifts to less crowded or otherwise more favourable environmental settings. To be sure, humans also have made such shifts when subjected to population and predatory pressures. Then, too, economic and military considerations often have been major driving factors in human expansion into new realms. Nonetheless, in numerous instances, human exploration has been marked by imaginative leaps across hostile stretches, sometimes at great risk, to reach something undefined simply for its own sake.

Much of the history of exploration—certainly of modern geographical exploration—has been European. Such has been the case not because Europeans possessed superior curiosity or some other internal force but because whatever events channelled their societies toward an advanced level of technology allowed them to expend more energy on exploration. The rapid growth and consolidation of their kingdoms provided them with an opportunity to exploit new discoveries fully. By contrast, the great Asian kingdoms, though no less capable, turned inward and erected walls—both legal and literal—between themselves and the "barbarians" of the outside world. The accomplishments of early European explorers are described in the article EUROPEAN OVERSEAS EXPLORATION AND EMPIRES, THE HISTORY OF.

The 20th century witnessed the last stages of exploration of the Earth's surface and the initial attempts to explore the deep sea and space. Scientific attention today is primarily directed toward these new frontiers. Efforts also are being made to investigate the interior of the Earth, knowledge of which still remains relatively limited. This article considers all three pursuits, highlighting the objectives, methods, and findings of each. (Da.D.)

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 723 and 738 and the *Index*.

The article is divided into the following sections:

Exploration of the Earth's surface and interior

By the beginning of the 20th century most of the Earth's surface had been explored, at least superficially, except for the Arctic and Antarctic regions.

Today the last of the unmarked areas on land maps have been filled in by radar and photographic mapping from aircraft and satellites. One of the last areas to be mapped was the Darién peninsula between the Panama Canal and Colombia. Heavy clouds, steady rain, and dense jungle vegetation made its exploration difficult, but airborne radar was able to penetrate the cloud cover to produce reliable, detailed maps of the area. In recent years data returned by Earth satellites have led to several notable discoveries, as, for example, drainage patterns in the Sahara, which are relics of a period when this region was not arid.

Historically, exploration of the Earth's interior was confined to the near surface, and this was largely a matter of following downward those discoveries made at the surface. Most present-day scientific knowledge of the subject has been obtained through geophysical research conducted since World War II, and the deep Earth remains a major frontier in the early 21st century.

Exploration of space and the ocean depths has been facilitated by the placement of sensors and related devices in these regions. Only a very limited portion of the subsurface regions of the Earth, however, can be studied in this way. Investigators can drill into only the uppermost crust, and the high cost of drilling is severely limiting. Because direct exploration is so restricted, investigators are forced to rely extensively on geophysical measurements (see below).

Problems of subsurface exploration

PRIMARY OBJECTIVES AND ACCOMPLISHMENTS

Scientific curiosity is a major motive for exploring the Earth's subsurface regions. Another key motive is the prospect of economic profit. Improved standards of living have increased the demand for water, fuel, and other materials, creating economic incentives. Pure knowledge has often been a by-product of profit-motivated exploration; by the same token, substantial economic benefits have resulted from the quest for scientific knowledge.

Many surface and subsurface exploratory projects are undertaken with the aim of locating: (1) oil and gas accumulations and coal beds; (2) concentrations of commercially important minerals (ores of iron, copper, and uranium) and deposits of building materials (sand, gravel, etc.); (3) recoverable groundwater; (4) various rock types at different depths for engineering planning; (5) geothermal reserves; and (6) archaeological features.

Concern for safety has prompted extensive searches for possible hazards before major construction projects are undertaken. Sites for dams, power plants, factories, tunnels, hazardous waste depositories, and so forth need to be stable and provide assurance that underlying formations will not shift or slide from the weight of the construction, move along a fault during an earthquake, or permit the seepage of water or wastes. Geophysical surveys furnish a more complete picture than test boreholes alone, although some boreholes are usually drilled to verify the geophysical interpretation.

METHODOLOGY AND INSTRUMENTATION

Geophysical techniques

Geophysical techniques involve measuring reflectivity, magnetism, gravity, acoustic or elastic waves, radioactivity, heat flow, electricity, and electromagnetism. Most measurements are made on the surface of the land or sea, but some are taken from aircraft or satellites, and still others are made underground in boreholes or mines and at ocean depths.

Geophysical mapping depends on the existence of a difference in physical properties of adjacent bodies of rock—*i.e.,* between whatever is being sought and those of the surroundings. Often the difference is provided by something associated with but other than whatever is being sought. Examples include a configuration of sedimentary layers that form a trap for oil accumulation, a drainage pattern that might affect groundwater flow, or a dike or host rock where minerals may be concentrated. Different methods depend on different physical properties. Which particular method is used is determined by what is being sought. In most cases, however, data from a combination of methods rather than from simply one method yield a much clearer picture.

Remote sensing. This comprises measurements of electromagnetic radiation from the ground, usually of reflected energy in various spectral ranges measured from aircraft or satellites. Remote sensing encompasses aerial photography and other kinds of measurements that are generally displayed in the form of photograph-like images. Its applications involve a broad range of studies, including cartographic, botanical, geological, and military investigations.

Fundamentals of remote sensing

Remote-sensing techniques involve using combinations of images. Images from different flight paths can be combined to allow an interpreter to perceive features in three dimensions, while those in different spectral bands may identify specific types of rock, soil, vegetation, and other entities, where species have distinctive reflectance values in different spectral regions (*i.e.,* tone signatures). Images taken at intervals make it possible to observe changes that occur over time, such as the seasonal growth of a crop or changes wrought by a storm or flood. Those taken at different times of the day or at different sun angles may reveal quite distinct features; for example, seafloor features in relatively shallow water in a calm sea can be mapped when the Sun is high. Radar radiation penetrates clouds and thus permits mapping from above them. Side-looking airborne radar (SLAR) is sensitive to changes in land slope and surface roughness. By registering images from adjacent flight paths, synthetic stereo pairs may give ground elevations.

Thermal infrared energy is detected by an optical-mechanical scanner. The detector is cooled by a liquid-nitrogen (or liquid-helium) jacket that encloses it, making the instrument sensitive at long wavelengths and isolating it from heat radiation from the immediate surroundings. A rotating mirror directs radiation coming from various directions onto the sensor. An image can be created by displaying the output in a form synchronized with the direction of the beam (as with a cathode-ray tube). Infrared radiation permits mapping surface temperatures to a precision of less than a degree and thus shows the effects of phenomena that produce temperature variations, such as groundwater movement.

Landsat images

Landsat images are among the most commonly used. They are produced with data obtained from a multispectral scanner carried aboard certain U.S. Landsat satellites orbiting the Earth at an altitude of about 900 kilometres (see also below *Applications satellites*). Images covering an area of 185 kilometres square are available for virtually every segment of the Earth's surface (see Plate 7). Scanner measurements are made in four spectral bands: green and red in the visible portion of the spectrum, and two infrared bands. The data are usually displayed by arbitrarily assigning different colours to the bands and then superimposing these to make "false-colour" images.

In geology, Landsat images are used to delineate landforms, rock outcrops and surface lithology, structural features, hydrothermal areas, and sites of mineral resources. Changes in vegetation revealed in the images may distinguish different soil types, subtle elevation differences, subsurface water distribution, subcropping rocks, and trace element distribution, among other things. Lineations of features may distinguish folded-rock strata or fault ruptures even where the primary features are not evident.

Magnetic methods. Measurements can be made of the Earth's total magnetic field or of components of the field in various directions. The oldest magnetic prospecting instrument is the magnetic compass, which measures the field direction. Other instruments include magnetic balances and fluxgate magnetometers. Most magnetic surveys are made with proton-precession or optical-pumping magnetometers, which are appreciably more accurate. The proton magnetometer measures a radio-frequency voltage induced in a coil by the reorientation (precession) of magnetically polarized protons in a container of ordinary water. The optical-pumping magnetometer makes use of the principles of nuclear resonance and cesium or rubidium vapour. It can detect minute magnetic fluctuations by measuring the effects of light-induced (optically pumped) transitions between atomic energy levels that are dependent on magnetic field strength.

Magnetic surveys from the air

Magnetic surveys are usually made with magnetometers borne by aircraft flying in parallel lines spaced two to four kilometres apart at an elevation of about 500 metres (one metre = 3.28 feet) when exploring for petroleum deposits and in lines 0.5 to one kilometre apart roughly 200 metres above the ground when searching for mineral concentrations. Ground surveys are conducted to follow up magnetic anomaly discoveries made from the air. Such surveys may involve stations spaced only 50 metres apart. Magnetometers also are towed by research vessels. In some cases, two or more magnetometers displaced a few metres from each other are used in a gradiometer arrangement; differences between their readings indicate the magnetic field gradient. A ground monitor is usually used to measure the natural fluctuations of the Earth's field over time so that corrections can be made. Surveying is generally suspended during periods of large magnetic fluctuation (magnetic storms).

Magnetics in petroleum and mineral prospecting

Magnetic effects result primarily from the magnetization induced in susceptible rocks by the Earth's magnetic field. Most sedimentary rocks have very low susceptibility and thus are nearly transparent to magnetism. Accordingly, in petroleum exploration magnetics are used negatively: magnetic anomalies indicate the absence of explorable sedimentary rocks. Magnetics are used for mapping features in igneous and metamorphic rocks, possibly faults, dikes, or other features that are associated with mineral concentrations. Data are usually displayed in the form of a contour map of the magnetic field, but interpretation is often made on profiles.

Rocks cannot retain magnetism when the temperature is above the Curie point (about 500° C for most magnetic materials), and this restricts magnetic rocks to the upper

40 kilometres of the Earth's interior. The source of the geomagnetic field must be deeper than this, and it is now believed that convection currents of conducting material in the outer core generate the field. These currents couple to the Earth's spin, so that the magnetic field—when averaged over time—is oriented along the planet's axis. The currents gradually change with time in a somewhat erratic manner and their aggregate effect sometimes reverses, which explains the time changes in the Earth's field. This is the crux of the magnetohydrodynamic theory of the geomagnetic field (see also EARTH: *Sources of the steady magnetic field*).

Gravimeters

Gravity methods. The gravity field of the Earth can be measured by timing the free fall of an object in a vacuum, by measuring the period of a pendulum, or in various other ways. Today almost all gravity surveying is done with gravimeters. Such an instrument typically consists of a weight attached to a spring that stretches or contracts corresponding to an increase or decrease in gravity. It is designed to measure differences in gravity accelerations rather than absolute magnitudes. Gravimeters used in geophysical surveys have an accuracy of about 0.01 milligal (mgal; 1 mgal = 0.001 centimetre per second per second). That is to say, they are capable of detecting differences in the Earth's gravitational ficld as small as one part in 100,000,000.

Gravity differences occur because of local density differences. Anomalies of exploration interest are often about 0.2 mgal. Data have to be corrected for variations due to elevation (one metre is equivalent to about 0.2 mgal), latitude (100 metres are equivalent to about 0.08 mgal), and other factors. Gravity surveys on land often involve meter readings every kilometre along traverse loops a few kilometres across. It takes only a few minutes to read a gravimeter, but determining location and elevation accurately requires much effort. Inertial navigation is sometimes used for determining elevation and location when helicopters are employed to transport gravimeters. Marine gravimeters are mounted on inertial platforms when used on surface vessels. A ship's speed and direction affcct gravimeter readings and limit survey accuracy. Aircraft undergo too many accelerations to permit gravity measurements except for regional studies.

In most cases, the density of sedimentary rocks incrcases with depth because the increased pressure results in a loss of porosity. Uplifts usually bring denser rocks nearer the surface and thereby create positive gravity anomalies. Faults that displace rocks of different densities also can cause gravity anomalies. Salt domes generally produce negative anomalies because salt is less dense than the surrounding rocks. Such folds, faults, and salt domcs trap oil, and so the detection of gravity anomalies associated with them is crucial in petroleum exploration. Moreover, gravity measurements are occasionally used to evaluate the amount of high-density mineral present in an ore body. They also provide a means of locating hidden caverns, old mine workings, and other subterranean cavities.

Seismic refraction methods. Seismic methods are based on measurements of the time interval between initiation of a seismic (elastic) wave and its arrival at detectors. The seismic wave may be generated by an explosion, a dropped weight, a mechanical vibrator, a bubble of high-pressure air injected into water, or other sources. The seismic wave is detected by a Geophone on land or by a hydrophone in water. An electromagnetic Geophone generates a voltage when a seismic wave produces relative motion of a wire coil in the field of a magnet, whereas a ceramic hydrophone generates a voltage when deformed by passage of a seismic wave. Data are usually recorded on magnetic tape for subsequent processing and display.

Seismic energy travels from source to detector by many paths. When near the source, the initial seismic energy generally travels by the shortest path, but as source-Geophone distances become greater, seismic waves travelling by longer paths through rocks of higher seismic velocity may arrive earlier (see Figure 1). Such waves are called head waves, and the refraction method involves their interpretation. From a plot of travel time as a function of source-Geophone distance, the number, thicknesses, and velocities of rock layers present can be determined for simple situations such as the one shown in Figure 2. The assumptions usually made are that (1) each layer is homogeneous and isotropic (*i.e.,* has the same velocity in all directions); (2) the boundaries (interfaces) between layers are nearly planar; and (3) each successive laycr has higher velocity than the one above. The velocity values determined from time-distance plots depend also on the dip (slope) of interfaccs, apparent velocities increasing whcn the Geophones are updip from the source and decreasing when downdip. By measuring in both directions the dip and rock velocity, each can be determined. With sufficicnt measurements, relief on the interfaces separating the layers also can be ascertained.

Fan shooting

High-velocity bodies of local extent can be located by fan shooting. Travel times are measured along different azimuths from a source, and an abnormally carly arrival time indicates that a high-velocity body was encountered at that azimuth. This method has been used to detcct salt domes, reefs, and intrusive bodies that are characterized by higher seismic velocity than the surrounding rock.

Two types of seismic waves can travel through a body: *P* waves (primary) and *S* waves (secondary). *P* waves are compressional waves and travel at the highest vclocity; hcnce, they arrive first. *S* waves are shcar waves that travel at a slower rate and are not able to pass through liquids that do not possess shear strength. In addition, there are

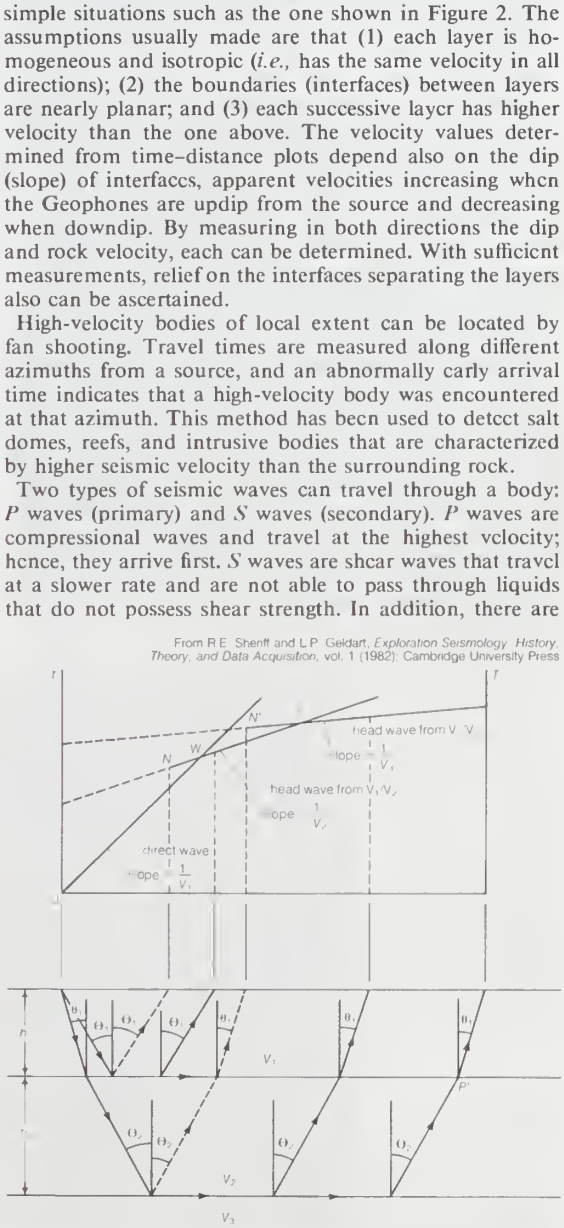

Figure 2: *Head waves from a three-layer situation.* (Top) Time–distance plot showing direct wave (*OW*) and head waves from the two interfaces (*NS* and *N'T*). (Bottom) Ray paths; $\Theta_1 = \sin^{-1}(V_1/V_2)$ = first critical angle, $\Theta_2 = \sin^{-1}(V_2/V_3)$ = second critical angle.

several types of seismic waves that can travel along surfaces. A major type of surface wave is the Rayleigh wave, in which a particle moves in an elliptical path in the vertical plane from the source. The horizontal component of Rayleigh waves is probably the principal cause of damage from earthquakes. Love waves are another type of surface wave; they involve shear motion. Still other varieties of surface waves can be transmitted through low-velocity layers (channel waves) or along the surface of a borehole (tube waves). Under certain circumstances (*e.g.*, oblique incidence on an interface), waves can change from one mode to another.

Significance of earthquake studies

Most of the current knowledge about the Earth's internal constitution is derived from analysis of the time–distance curves from earthquakes. Earthquakes usually generate several wave modes. These refract and reflect at interfaces within the Earth and partially change to other wave types to add to the number of seismic waves resulting from an earthquake. Different wave types can sometimes be distinguished by their components of motion detected by three-component seismographs; the direction from which they come can be determined by using an array of seismographs at the receiving station or by combining the data from different stations. The first wave motion from an earthquake reveals the nature of earth motion involved in the earthquake.

Very shallow seismic refraction is extensively used in engineering studies. Sometimes the energy source for shallow-penetration engineering studies involves simply hitting the ground with a sledgehammer. The ease with which a rock can be ripped by a bulldozer relates to the rock's seismic velocity. *S*-wave velocity measurements are of special interest to engineers because building stability depends on the shear strength of the foundation rock or soil. Seismic waves may be used for various other purposes. They are employed, for example, to detect faults that may disrupt a coal seam or fractures that may allow water penetration into a tunnel.

Seismic reflection methods. Most seismic work utilizes reflection techniques. Sources and Geophones are essentially the same as those used in refraction methods. The concept is similar to echo sounding: seismic waves are reflected at interfaces where rock properties change and the round-trip travel time, together with velocity information, gives the distance to the interface. The relief on the interface can be determined by mapping the reflection at many locations. For simple situations the velocity can be determined from the change in arrival time as source–Geophone distance changes.

In practice, the seismic reflection method is much more complicated. Reflections from most of the many interfaces within the Earth are very weak and so do not stand out against background noise. The reflections from closely spaced interfaces interfere with each other. Reflections from interfaces with different dips, seismic waves that bounce repeatedly between interfaces ("multiples"), converted waves, and waves travelling by other modes interfere with desired reflections. Also, velocity irregularities bend seismic rays in ways that are sometimes complicated.

The objective of most seismic work is to map geologic structure by determining the arrival time of reflectors (see Figure 3). Changes in the amplitude and waveshape, however, contain information about stratigraphic changes and occasionally hydrocarbon accumulations. In some cases, seismic patterns can be identified with depositional systems, unconformities, channels, and other features.

Advantage of seismic reflection

The seismic reflection method usually gives better resolution (*i.e.*, makes it possible to see smaller features) than other methods, with the exception of measurements made in close proximity, as with borehole logs (see below). Appreciably more funds are expended on seismic reflection work than on all other geophysical methods combined.

Electrical and electromagnetic methods. A multitude of electrical methods are used in mineral exploration. They depend on (1) electrochemical activity, (2) resistivity changes, or (3) permittivity effects. Some materials tend to become natural batteries that generate natural electric currents whose effects can be measured. The self-potential method relies on the oxidation of the upper surface of metallic sulfide minerals by downward-percolating groundwater to become a natural battery; current flows through the ore body and back through the surrounding groundwater, which acts as the electrolyte. Measuring the natural voltage differences (usually 50–400 millivolts [mV]) permits detecting continuous metallic sulfide bodies that lie astride the water table. Graphite, magnetite, anthracite, some pyritized rocks, and other phenomena also can generate self-potentials.

Self-potential method

The passage of an electric current across an interface where conduction changes from ionic to electronic results in a charge buildup at the interface. This charge builds up shortly after current flow begins, and it takes a short time to decay after the current circuit is broken. Such an effect is measured in induced-polarization methods and is used to detect sulfide ore bodies.

Resistivity methods involve passing a current from a generator or other electric power source between a pair of current electrodes and measuring potential differences

The vertical scale is reflection arrival time. Section shows several faults indicated by disruptions in the reflections. At the right end of the section are a gas field at 1.350 seconds and an oil field at 2.200 seconds.

with another pair of electrodes. Various electrode configurations are used to determine the apparent resistivity from the voltage/current ratio. The resistivity of most rocks varies with porosity, the salinity of the interstitial fluid, and certain other factors. Rocks containing appreciable clay usually have low resistivity. The resistivity of rocks containing conducting minerals such as sulfide ores and graphitized or pyritized rocks depends on the connectivity of the minerals present. Resistivity methods also are used in engineering and groundwater surveys, because resistivity often changes markedly at soil/bedrock interfaces, at the water table, and at a fresh/saline water boundary.

Investigators can determine how resistivity varies over a given area by means of profiling methods, in which the location of an array of electrodes is altered but the same spacing between the component electrodes is maintained. Sounding methods enable investigators to pinpoint variations of resistivity with depth. In this case, electrode spacing is increased and, correspondingly, the effective depth of the contributing section. Several other techniques are commonly employed. Equipotential methods entail mapping equipotential lines that result from a current. Distortions from a systematic pattern indicate the presence of a body of different resistivity. The mise-a-la-masse method involves putting one current electrode in an ore body in order to map its shape and location.

The passage of current in the general frequency range of 500–5,000 hertz (Hz) induces in the Earth electromagnetic waves of long wavelength, which have considerable penetration into the Earth's interior. The effective penetration can be changed by altering the frequency. Eddy currents are induced where conductors are present, and these currents generate an alternating magnetic field, which induces in a receiving coil a secondary voltage that is out of phase with the primary voltage. Electromagnetic methods involve measuring this out-of-phase component or other effects, which makes it possible to locate low-resistivity ore bodies wherein the eddy currents are generated.

Magnetotelluric and related methods

Natural currents are induced in the Earth as a result of atmospheric disturbances (*e.g.,* lightning strikes) and bombardment of the upper atmosphere by the solar wind—a radial flow of protons, electrons, and nuclei of heavier elements emanating from the outer region of the Sun. Magnetotelluric methods measure orthogonal components of the electric and magnetic fields induced by these natural currents. Such measurements allow researchers to determine resistivity as a function of depth. The natural currents span a broad range of frequencies and thus a range of effective penetration depths. Related to the above techniques is the telluric-current method, in which the electric current variations are measured simultaneously at two stations. Comparison of the data permits determining differences in the apparent resistivity with depth at the two stations.

Electrical methods generally do not penetrate far into the Earth, and so do not yield much information about its deeper parts. They do, however, provide a valuable tool of exploring for many metal ores.

In addition, several electrical methods are used in boreholes. The self-potential (SP) log indicates mainly clay (shale) content, because an electrochemical cell is established at the shale boundary when the salinity of the borehole (drilling) fluid differs from that of the water in the rock. Resistivity measurements are made by using several electrode configurations and also by induction. Borehole methods are used to identify the rocks penetrated by a borehole and to determine their properties, especially their porosity and the nature of their interstitial fluids.

Radioactive methods. Radioactive surveys are used to detect ores or rock bodies associated with radioactive materials. Most natural radioactivity derives from uranium, thorium, and a radioisotope of potassium (potassium-40), as well as from radon gas. Radioactive elements are concentrated chiefly in the upper portion of the Earth's crust.

Radioactive disintegration, or decay, gives rise to spontaneous emission of alpha and beta particles and gamma rays. Detection is usually of gamma rays, and it is accomplished in most cases with a scintillometer, a photoconversion device containing a crystal of sodium iodide that emits a photon (minute packet of electromagnetic radiation) when struck by a gamma ray. The photon, whose intensity is proportional to the energy of the gamma ray, causes an adjacent photocathode to emit electrons, the exact number depending on the energy of the photon. The energy of the gamma ray itself is determined by the nature of the radioactive disintegration involved.

Where it can be assumed that a product element of a radioactive disintegration (a daughter isotope) is derived solely from the disintegration of a parent isotope that occurred after a rock's solidification (*i.e.,* as the rock cooled through its Curie point), the ratio of the parent/daughter isotopes present depends on the time since solidification. This often provides the basis for age determinations of rocks.

Gamma-ray logging

Information about the mineral composition and physical properties of a rock formation can be obtained by means of gamma-ray logging, a technique that involves measuring natural gamma-ray emissions in boreholes. In most sedimentary rocks, for example, potassium-40 is the principal emitter of gamma rays. Because potassium is generally associated with clays, a recording of gamma-ray emissions permits determination of clay (shale) content. In another related technique, the rock surrounding a borehole is bombarded by a radioactive source in the logging sonde and the effects of the reactions caused by the bombardment are measured. In a density log measurements are made of gamma rays that are backscattered from the rock formation, since their intensity indicates rock density. A neutron source is employed in another type of borehole log, one that is designed to reveal how much fluid occurs in a rock formation or how porous it is. Neutron energy loss is directly related to the density of protons (hydrogen nuclei) in rock, which is in turn reflective of its water content (or degree of porosity).

Geothermal methods. Temperature-gradient measurements are sometimes made to detect heat-flow anomalies; however, most exploration for geothermal resources (*e.g.,* superheated water and steam) is done with indirect methods. Resistivity or seismic methods, for example, may be used to map the magma chamber, which is the source of the heat, or to detect faults or other features that control the flow of hot subsurface water.

Measurement of trace elements

Geochemical methods. Since the early 1970s researchers have developed extremely sensitive methods of chemical analysis, providing the ability to detect minute amounts of materials. Many chemical elements are transported in very small quantities by fluids flowing in the Earth, so that a systematic measurement of such trace elements may help in locating their sources. Trace elements are sometimes associated with hydrocarbons (the principal constituents of petroleum, natural gas, and other fossil fuels); they can be utilized for identifying the specific types of hydrocarbons present in a given area.

Excavation, boring, and sampling. Direct sampling, usually by means of boreholes, is required to make positive identification of ores, fuels, and other materials. It is also necessary for determining their quantity and for selecting methods of recovery. Most deep boreholes are drilled by the rotary method, in which a drill bit is rotated while fluid ("drilling mud") is circulated through the bit to lubricate and cool it and to bring rock chips to the surface where they can be collected and analyzed. Shallow boreholes in hard rock formations are sometimes drilled by a percussion method, whereby a heavy bit is repeatedly raised and dropped to chip away pieces of rock. After a borehole has been drilled, various tools—sondes—are lowered into the hole to measure different physical properties.

CONCLUSIONS ABOUT THE DEEP EARTH

The overall oblate shape of the Earth was established by French Academy expeditions between 1735 and 1743. The Earth's mean density and total mass were determined by the English physicist and chemist Henry Cavendish in about 1797. It was later ascertained that the density of rocks on the Earth's surface is significantly less than the mean density, leading to the assumption that the density of the deeper parts of the planet must be much greater.

The Earth's magnetic field was first studied by William

Gilbert of England during the late 1500s. Since that time a long sequence of measurements has indicated its overall dipole nature, with ample evidence that it is more complex than the field of a simple dipole. Investigators also have demonstrated that the geomagnetic field changes over time. Moreover, they have found that magnetic constituents within rocks take on magnetic orientations as the rocks cool through their Curie point or, in the case of sedimentary rocks, as they are deposited. A rock tends to retain its magnetic orientation, so that measuring it provides information about the Earth's magnetic field at the time of the rock's formation and how the rock has moved since then. The field of study specifically concerned with this subject is called paleomagnetism.

Observations of earthquake waves by the mid-1900s had led to a spherically symmetrical crust–mantle–core picture of the Earth (see Figure 4). The crust–mantle boundary is marked by a fairly large increase in velocity at the Mohorovičić discontinuity at depths on the order of 25–40 kilometres on the continents and five–eight kilometres on the seafloor. The mantle–core boundary is the Gutenberg discontinuity at a depth of about 2,800 kilometres. The outer core is thought to be liquid because shear waves do not pass through it.

Concept of plate tectonics

Scientific understanding of the Earth began undergoing a revolution from the 1950s. Theories of continental drift and seafloor spreading evolved into plate tectonics, the concept that the upper, primarily rigid part of the Earth, the lithosphere, is floating on a plastic asthenosphere and that the lithosphere is being moved by slow convection currents in the upper mantle. The plates spread from the mid-oceanic ridges where new oceanic crust is being formed, and they are destroyed by plunging back into the asthenosphere at subduction zones where they collide. Lithospheric plates also may slide past one another along strike-slip or transform faults (see also PLATE TECTONICS). Most earthquakes occur at the subduction zones or along strike-slip faults, but some minor ones occur in rift zones. The apparent fit of the bulge of eastern South America into the bight of Africa, magnetic stripes on the ocean floors, earthquake distribution, paleomagnetic data, and various other observations are now regarded as natural consequences of a single plate-tectonics model. The model has many applications; it explains much inferred Earth history and suggests where hydrocarbons and minerals are most likely to be found. Its acceptance has been widespread as economic conclusions have borne fruit.

An extensive series of boreholes drilled into the seafloor under the Joint Oceanographic Institutions for Deep Earth Sampling (JOIDES) program has established a relatively simple picture of the crust beneath the oceans (see also below *Undersea exploration*). In the rift zones where the plates comprising the Earth's thin crust separate, material from the mantle wells upward, cools, and solidifies. The molten mantle material that flows onto the seafloor and cools rapidly is called pillow basalt, while the underlying material that cools more slowly forms what is termed sheeted gabbro dikes. Sediments gradually accumulate on top of these, producing a comparatively simple pattern of sediment, basaltic basement, and gabbroic layering. Much of the heat flow from the solid Earth into the oceans results from the slow cooling of the oceanic basement rocks. Heat flow gradually declines with distance from the spreading centres (or with the length of time since solidification). As the oceanic rocks cool they become slightly denser, and isostatic adjustment causes them to subside slightly so that oceanic depths become greater. The oceanic crust is relatively thin, measuring only about five–eight kilometres in thickness. Nearly all oceanic rocks are fairly young, mostly Jurassic or younger (*i.e.*, less than 190,000,000 years old).

Seismic investigation of the continental crust

The crust beneath the continents, unlike the oceanic crust, is considerably older and thicker and appears to have been formed in a much more complex way. Because of its greater thickness, diversity, and complexity, the continental crust is much more difficult to explore. In 1975 the U.S. Geodynamics Committee initiated a research program to explore the continental crust using seismic techniques developed by private industry for the purpose of locating petroleum accumulations in sedimentary rocks. Since then its investigations have been conducted in a number of locales throughout the United States. Several notable findings have resulted from these studies, the most spectacular of which was the discovery of a succession of very low-angle thrust sheets beneath the Appalachian Mountains. This discovery, made from seismic data collected across this region between 1978 and 1980, is altering prevailing theories on continent formation.

The success of the U.S. crustal studies program has spawned a series of similar efforts in Australia, Europe, India, and elsewhere, and seismic investigation of the continental crust continues to be one of the most active areas of basic exploration in the last quarter of the 20th century.

The desire to detect nuclear explosions in the years following World War II led to the establishment of a worldwide network of uniform seismograph stations. This has greatly increased the number and reliability of earthquake measurements, the major source of information about the Earth's interior. The construction of large-array seismograph stations has made it possible to determine the directions of approach of earthquake waves and to sort out overlapping wave trains. Computer processing allows investigators to separate many wave effects from background noise and to analyze the implications of the multitude of observations now available.

The assumptions made in the past that significant property variations occur mainly in the vertical direction were clearly an oversimplification. Today, investigation of the deep Earth concentrates primarily on determining lateral (horizontal) changes and on interpreting their significance. Seismic tomographic analysis (see above) indicates appreciable variation in properties, many of which tend to confirm what is expected from theories about upper mantle convection currents. The data, however, also indicate variations whose significance has yet to be determined.

(R.E.Sh.)

Undersea exploration

PRIMARY OBJECTIVES AND ACCOMPLISHMENTS

The objectives of undersea exploration are to describe and understand the ocean waters, the seafloor, and the Earth beneath. Included in the scope of study are the physical and chemical properties of seawater, all manner of life in the sea, and the geological and geophysical features of the Earth's crust. Researchers in the field define and measure such properties; prepare maps in order to identify patterns; and utilize these maps, measurements, and theoretical models to achieve a better grasp of how the Earth works as a whole. This knowledge enables scientists to predict, for example, long-term weather and climatic changes and leads to more efficient exploration and exploitation of the Earth's resources, which in turn result in better management of the environment in general.

The multidisciplinary expedition of the British ship

First major undersea survey

"Challenger" in 1872–76 was the first major undersea survey. Although its main goal was to search for deep-sea life by means of net tows and dredging, the findings of its physical and chemical studies expanded scientific knowledge of temperature and salinity distribution of the open seas. Moreover, depth measurements by wire soundings were carried out all over the globe during the expedition.

Since the time of the "Challenger" voyage, scientists have learned much about the mechanics of the ocean, what it contains, and what lies below its surface. Investigators have produced global maps showing the distribution of surface winds as well as of heat and rainfall, which all work together to drive the ocean in its unceasing motion. They have discovered that storms at the surface can penetrate deep into the ocean and, in fact, cause deep-sea sediments to be rippled and moved. Recent studies also have revealed that storms called eddies occur within the ocean itself and that such a climatic anomaly as El Niño is caused by an interaction of the ocean and the atmosphere.

Other investigations have shown that the ocean absorbs large amounts of carbon dioxide and hence plays a major role in delaying its buildup in the atmosphere. Without the moderating effect of the ocean, the steadily increasing input of carbon dioxide into the atmosphere (due to the extensive burning of coal, oil, and natural gas) would result in the rapid onset of the so-called greenhouse effect—*i.e.*, a warming of the Earth caused by the absorption and reradiating of infrared energy to the terrestrial surface by carbon dioxide and water vapour in the air.

The field of marine biology has benefitted from the development of new sampling methods. Among these, broad ranging acoustical techniques have revealed diverse fish populations and their distribution, while direct, close up observation made possible by deep-sca submersibles has resulted in the discovery of unusual (and unexpected) species and phenomena.

In the area of geology, undersea exploration of the topography of the seafloor and its gravitational and magnetic properties has led to the recognition of global patterns of continental plate motion. These patterns form the basis of the concept of plate tectonics, which synthesized earlier hypotheses of continental drift and seafloor spreading. As noted earlier, this concept not only revolutionized scicntific understanding of the Earth's dynamic features (*e.g.*, seismic activity, mountain-building, and volcanism) but also yielded discoveries of economic and political impact. Earth scientists found that the mid-ocean centres of seafloor spreading also are sites of important metal deposits. The hydrothermal circulations associated with these centres produce sizable accumulations of metals important to the world economy, including zinc, copper, lead, silver, and gold. Rich deposits of manganese, cobalt, nickel, and other commercially valuable metals have been found in nodules distributed over the entirc ocean floor. The latter discovery proved to be a major factor in the establishment of the Convention of the Law of the Sea (1982), which calls for the sharing of these resources among developed and developing nations alike. Exploitation of these findings awaits only the introduction of commercially viable techniques for deep-sea mining and transportation.

Discovery of metal deposits on the seafloor

BASIC ELEMENTS OF UNDERSEA EXPLORATION

Platforms. Undersea exploration of any kind must be conducted from platforms, in most cases, ships, buoys, aircraft, or satellites. Typical oceanographic vessels capable of carrying out a full complement of underwater exploratory activities range in size from about 50 to 150 metres. They support scientific crews of 16 to 50 persons and generally permit a full spectrum of interdisciplinary studies. One example of a research vessel of this kind is the "Melville," operated by the Scripps Institution of Oceanography. It has a displacement of 2,075 tons and can carry 25 scientists in addition to 25 crew members. It is powered by a dual cycloidal propulsion system, which provides remarkable manoeuvrability.

Decp-sea drilling vessel

The "JOIDES Resolution," operated by Texas A & M University for the Joint Oceanographic Institutions for Deep Earth Sampling, represents a major advance in research vessels. A converted commercial drill ship, it measures 145 metres in length, has a displacement of 18,600 tons, and is equipped with a derrick that extends 62 metres above the waterline (see Figure 5). A computer-controlled dynamic positioning system enables the ship to remain over a specific location while drilling in water to depths as great as 8,300 metres. The drilling system of the ship is designed to collect cores from below the ocean floor; it can handle 9,200 metres of drill pipe. The vessel thus can sample most of the ocean floor, including the bottoms of deep ocean basins and trenches. The "JOIDES Resolution" has other notable capabilities. It can operate in waves as high as eight metres, winds up to 23 metres per second, and currents as strong as 1.3 metres per second. It has been outfitted for use in ice so that it can conduct drilling operations in high latitudes. The ship can accommodate 50 scientists as well as the crew and drilling team, and its geophysical laboratories total nearly 930 square metres.

Sub-mersibles

Other specialized vessels include the deep submergence research vehicle known as "Alvin" (see Figure 6), which can carry a pilot and two scientific observers to a depth of 4,000 metres. The manoeuvrability of the "Alvin" was pivotal to the discoveries of the mineral deposits at the mid-ocean seafloor spreading centres and of previously unknown biological communities living at those sites. Another versatile vessel is the Floating Instrument Platform (FLIP). It is a long narrow platform that is towed in a horizontal position to a research site. Once on location, the ballast tanks arc flooded to flip the ship to a vertical position. Only 17 metres of the ship extend above the waterline, with the remaining 92 metres completely submerged. The rise and fall of the waves cause a very small change in the displacement, resulting in a high degree of stability.

New ship designs that promise even greater stability and ease of use include that of thc Small Waterplane Area Twin Hull (SWATH) variety. This design type requircs the use of twin submerged, streamlined hulls to support a structure that rides above the watcr surface. The deck shape is entirely unconstrained by the hull shape, as is the case for conventional surface vessels. Ship motion is

greatly reduced because of the depth of the submerged hulls. For a given displacement, a SWATH-type vessel can provide twice the amount of deck space that a single-hull ship can, with only 10 percent of the motion of the single-hull design type. In addition, a large centre opening, or well, can be used to display and recover instruments.

Navigation. Exploration of any kind is useful only when the location of the discoveries can be noted precisely. Thus, navigation has always been a key to undersea exploration.

There are various ways by which the position of a vessel at sea can be determined. In cases where external references such as stars or radio and satellite beacons are unavailable or undetectable, inertial navigation, which relies on a stable gyroscope for determining position, is commonly employed. It is far more accurate than the long-used technique of dead reckoning, which is dependent on a knowledge of the ship's original position and the effects of the winds and ocean currents on the vessel.

Loran systems

Another modern position-fixing method is all-weather, long-range radio navigation. It was introduced during World War II as Loran (long-range navigation) A, a system that determines position by measuring the difference in the time of reception of synchronized pulses from widely spaced transmitting stations. The latest version of this system, Loran C, uses low-frequency transmissions and derives its high degree of accuracy from precise time-difference measurements of the pulsed signals and the inherent stability of signal propagation. Users of Loran C are able to identify a position with an accuracy of 0.4 kilometre and a repeatability of 15 metres at a distance of up to about 2,220 kilometres from the reference stations. The Loran C system covers heavily travelled regions in the North Pacific and North Atlantic oceans, parts of the Indian Ocean, and the Mediterranean Sea.

Satellite navigation

Satellite navigation has proved to be the most accurate method of locating geographical position. A polar-orbiting satellite system called Transit was established in the early 1960s by the United States to provide global coverage for ships at sea. In this system, a vessel pinpoints its position relative to a set of satellites whose orbits are known by measuring the Doppler shift of a received signal—*i.e.*, the change in the frequency of the received signal from that of the transmitted signal. The Transit system suffers from one major drawback. Because of the limited number of system satellites, the frequency with which position determinations can be made each day is relatively low, particularly in the tropics. The system is being improved to provide nearly continuous positioning capability at sea. This expanded version, the Global Positioning System (GPS), is to have 18 satellites, six in each of three orbital planes spaced 120° apart. The GPS is designed to provide fixes anywhere on Earth to an accuracy of 20 metres and a relative accuracy 10 times greater.

METHODOLOGY AND INSTRUMENTATION

Water sampling for temperature and salinity. The temperature, chemical environment, and movement and mixing of seawater are fundamental to understanding the physical, chemical, and biological features of the ocean and the geology of the ocean floor. Traditionally, oceanographers have collected seawater by means of specially adapted water-sampling bottles. The most universal water sampler used today, the Nansen bottle, is a modification of a type developed in the latter part of the 19th century by the Norwegian Arctic explorer and oceanographer Fridtjof Nansen. It is a metal sampler equipped with special closing valves that are actuated when the bottle, attached by one end to a wire that carries it to the desired depth, rotates about that end. A mercury thermometer fastened to the bottle records the temperature at the specified depth. The design of the device is such that, when it is inverted, its mercury column breaks. The amount of mercury remaining in the graduated capillary portion of the thermometer indicates the temperature at the point of inversion. This type of reversing thermometer and the Nansen bottle are extensively used by oceanographers because of their accuracy and dependability in a harsh environment.

The temperature and salinity of the ocean have been mapped with data gathered by many ships over many years. This information is used for tracing heat and water movement and mixing, as well as for making density measurements, which are employed in calculating ocean currents. It was noted as early as the "Challenger" expedition that the salt dissolved in seawater has remarkably constant major constituents. As a consequence, it is possible to map water density patterns within the sea with measurements of only the water temperature and one major property of the sea salt (*e.g.*, the chloride ion content or the electrical conductivity) to arrive at an accurate estimate of the density of a given sample.

The concept of standard seawater

Standard laboratory techniques such as titration are routinely used at sea for determining chlorinity. Chlorinity can be briefly defined as the number of grams of chlorine, bromine, and iodine contained in one kilogram of seawater, assuming that the bromine and iodine are replaced by chlorine. Salinity is the total weight of dissolved solids, in grams, found in one kilogram of seawater and may be determined from the concentration of chlorinity because of the constancy of major constituents. In the traditional technique, a solution of silver nitrate of a known strength is added to a sample of seawater to produce the same reaction as with "standard" seawater. The difference in the amounts added gives the degree of chlorinity. To ensure worldwide uniformity in chlorinity and salinity determinations, the International Council for the Exploration of the Sea prepared a universal reference, *Eau de Mer Normale* ("Standard Seawater"), in 1902. A new primary standard, prepared in 1937 and having a chlorinity of 19.381 parts per 1,000, is used to determine the chlorinities of all batches of standard seawater. It also is utilized to calibrate electrical conductivity measurements (see below).

Bathythermographs

Accurate and continuous measurements of temperature as it changes with depth are required for understanding how the ocean moves and mixes heat. To provide the necessary detail, temperature profilers had to be developed; then, with the introduction of reliable conductivity sensors, salinity profilers were added. An instrument called the bathythermograph (BT), which has been used since the early 1940s to obtain a graphic record of water temperature at various depths, can be lowered from a ship while it is moving at reduced speed. In this instrument a depth element (pressure-operated bellows) drives a slide of smoked glass or metal at right angles to a stylus. Actuated by a thermal element (liquid-filled bourdon tube) that expands and contracts in response to changes in temperature, the stylus scribes a continuous record of temperature and depth.

An expendable bathythermograph (XBT) was developed during the 1970s and has come into increasingly wider use. Unlike the BT, this instrument requires an electrical system aboard the research platform. It detects temperature variations by means of a thermistor (an electrical resistance element made of a semiconductor material) and depends on a known fall rate for depth determination. The sensor unit of the XBT is connected to the research platform by a leak-proof, insulated two-conductor cable. This cable is wound around a pair of large spools in an arrangement resembling that of a fisherman's spinning reel. In operation, the cable is unwound from each of the spools in a direction that is parallel to the axis of the respective spool. As a result, the cable unwinds from both the platform—either a ship or an airplane—and the sensor unit simultaneously but independently. Because of this double-spool arrangement, the sensor unit can free-fall from wherever it hits the sea surface and is completely unaffected by the direction or speed of the craft from which it was deployed. One of the principal reasons why the XBT has proved so useful is that it can provide a record of considerable depth even when it is deployed from a ship moving at full speed.

Electrical conductivity systems

Until the late 1950s, salinity was universally determined by titration. Since then, shipboard electrical conductivity systems have become widely used. Salinity-Temperature-Depth (STD) and the more recent Conductivity-Temperature-Depth (CTD) systems have greatly improved on-site hydrographic sampling methods. They have enabled oceanographers to learn much about small-scale temperature and salinity distributions.

The most recent version of the CTD systems features rapid-response conductivity and temperature sensors. The conductivity sensor consists of a tiny cell with four platinum electrodes. This type of conductivity cell virtually eliminates errors resulting from the polarization that occurs where the electrodes come in contact with seawater. The temperature sensor combines a tiny thermistor with a platinum-resistance thermometer. Its operations are carried out in such a way as to fully exploit the fast response of the thermistor and the high accuracy of the platinum thermometer. In addition, the system uses a strain gauge as a pressure sensor, the gauge being adjusted to reduce temperature effects to a minimum. This CTD system is extremely reliable. While its temperature precision is greater than 0.001° C over a range of −3° to +32° C, its conductivity precision is on the order of one part per million.

Electrical conductivity measurement of seawater salinity has been so effective that it has given rise to a new practical salinity scale, one that is defined on the basis of conductivity ratio. This scale has proved to be a more reliable way of determining density (*i.e.,* the weight of any given volume of seawater at a specified temperature) than the chlorinity scale traditionally used. Such is the case because chlorinity is ion specific while conductivity is sensitive to changes in any ion. Investigators have found that measurements of conductivity ratio make it possible to predict density with a precision almost one order of magnitude greater than was permitted by the chlorinity measurements of the past.

Studying dissolved gases in seawater

Water sampling for chemical constituents. Nutrient concentration (*e.g.,* phosphate, nitrate, silicate), the pH (acidity), and the proportion of dissolved gases are used by the ocean chemist to determine the age, origin, and movement of water masses and their effect on marine life. Analysis of dissolved gases, for example, is useful in tracing ocean mixing, in studying gas production in the ocean, and in elucidating the natural cycles of atmospheric pollutants. Many such measurements are conducted aboard ship by autoanalyzers, devices that continually monitor a flow of seawater by spectral techniques. Those analyses that cannot be accomplished by an autoanalyzer are carried out with discrete samples in shipboard or shore-based laboratories.

Radioactive chemical tracers are of special interest. Radioisotopes serve as time clocks, thus offering a means of determining the age of water masses, the absolute rates of oceanic mixing, and the generation and destruction of plant tissue. The distribution of these time clocks is controlled by the interaction of physical and biological processes, and so these influences must be disentangled before the clocks can be read. A notable example is the use of carbon-14 (^{14}C). Today, a number of oceanographic laboratories make carbon-14 measurements of oceanic dissolved carbon for the study of mixing and transport processes in the deep ocean. Until recently large samples of water—about 200 litres (one litre = 0.264 gallon)—were required for analysis. New techniques use a linear accelerator (a device that greatly increases the velocity of electrically charged atomic and subatomic particles) as a sophisticated mass spectrometer to directly determine abundancy ratios of carbon-14/carbon-13/carbon-12 atoms. The advantage of the newer methodology is that only very small sample amounts—about 250 millilitres (one millilitre = 0.034 fluid ounce), are required for high accuracy measurements.

Measurements of ocean currents. Ocean currents can be measured indirectly through data on density and directly with current meters. In the indirect technique, water density is computed from temperature and salinity observations, and pressure is then calculated from density. The resulting highs and lows of ocean pressure can be used to estimate ocean currents. The indirect technique establishes currents relative to a particular pressure surface; it is best for large-scale, low-frequency currents.

Direct measurement of currents is used to establish absolute currents and to monitor rapidly varying changes. In order to measure currents directly, a current meter must accurately record the speed and direction of flow, and the platform or mooring has to be reliable, readily deployable, and extremely sturdy. Researchers are able to make continuous measurements of currents at levels below the surface layer for periods of more than a year.

A typical system for the direct measure of ocean currents (see Figure 7) has three principal components: a surface or near-surface float; a line consisting of segments of wire and nylon that holds the current meters; and a release mechanism, signalled acoustically, which will drop an anchor when the system is ready to be brought back. A current meter typically employs a rotor equipped with a small direction vane that moves freely in line with the meter.

Impact of technological advances

One of the most important advances in modern instrument design has been the introduction of low-power, solid-state microelectronics. The accuracy of the Vector Averaging Current Meter (VACM), for example, has been

By courtesy of Woods Hole Oceanographic Institution

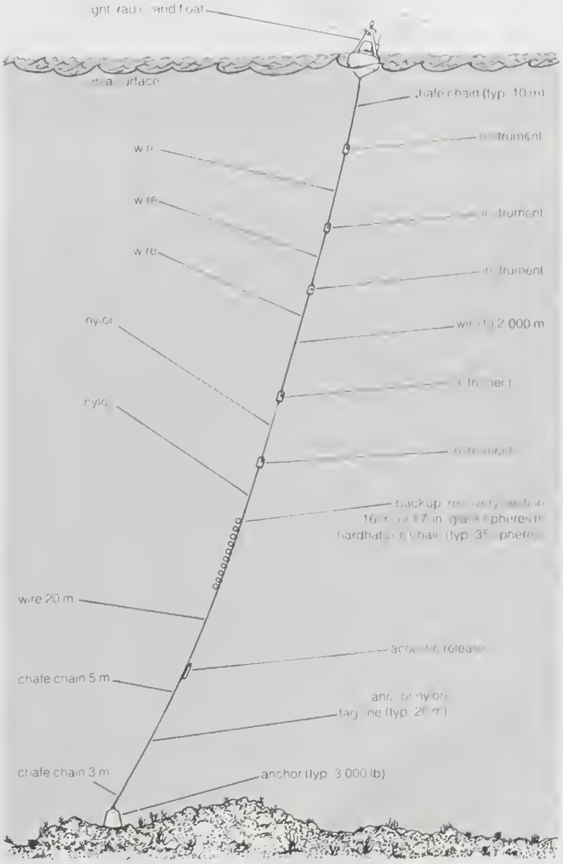

Figure 7: The surface mooring configuration used for measuring ocean currents in the deep sea by the Woods Hole Oceanographic Institution Buoy group.

improved appreciably by the use of integrated circuits, as has its data-handling capability. Because of the latter, the VACM can sample the direction and speed of currents roughly eight times during each revolution of the rotor. It then computes the north and east components of speed and stores this data, together with direction and time measurements, on a compact cassette recorder. The VACM is capable of making accurate measurements in wave fields as well as from moorings at the ocean surface because of its direct vector-averaging feature.

Currents also can be measured by drifting floats, either at the surface or at a given depth. Tracking the location of the floats is critical. Surface floats can be followed by satellite, but subsurface drifters must be tracked acoustically. A drifter of this sort acts as an acoustical source and transmits signals that can be followed by a ship with hydrophones suspended into the sea. For such tracking, a low sound frequency is crucial because the higher the frequency of sound, the more rapidly is its energy absorbed by the sea. The longest range floats available during the mid-1980s operated at a frequency as low as about 250 hertz. Long-range floats usually drift along channels known as sound fixing and ranging (SOFAR) channels, which occur in various areas of the ocean where a particular combination of temperature and pressure conditions affect the speed of sound. In a sense, the SOFAR channel acts as a type of acoustic waveguide that focusses sound; as a consequence, several watts of sound can be detected as far away as 2,000 kilometres or so.

Measuring vertical velocity in the ocean posed a major problem for years because of the difficulty of devising a platform that does not move vertically. During the 1960s oceanographers finally came up with a solution: they employed a neutrally buoyant float for measuring vertical velocities. This form of vertical-current meter consists of a cylindrical float on which fins are mounted at an angle. When water moves past the float, it causes the float to turn on its axis. Measurement of the rotation in relation to a compass yields the amount of vertical water movement.

Vertical-current meter

An extension of the neutrally buoyant float is the self-propelled, guided float. One such system, called a Self-Propelled Underwater Research Vehicle (SPURV), manoeuvres below the surface of the sea in response to acoustic signals from the research vessel. It can be used to produce horizontal as well as vertical profiles of various physical properties.

A Doppler-sonar system for measuring upper-ocean current velocity transmits a narrow beam that scatters off drifting plankton and other organisms in the uppermost strata of the ocean. From the Doppler shift of the backscattered sound, the component of water velocity parallel to the beam can be determined to a range of 1,400 metres from the transmitter with a precision of one centimetre per 0.1 second (one centimetre = 0.394 inch).

Integral to a complete picture of the ocean is a profile of velocity. Various methods have been devised for measuring currents as dependent on and varying with depth or horizontal position. Three techniques have been developed to make such measurements. The first involves acoustically tracking a "sinking float" as it descends toward the seafloor. The second technique entails the use of a free-fall device equipped with a current sensor. The third involves a class of current meter specially designed to move up and down a fixed line attached to a vessel, mooring, or drifting buoy. One such instrument has a roller block that couples the front of the instrument to a wire from the vessel. In this way, the motion of the vessel is decoupled from that of the instrument. Another important component of this instrument is its hull, a structure that not only furnishes buoyancy but also serves as a direction vane. In the bottom of the hull is a device that records velocity, temperature, and depth. The entire system descends at a rate of approximately 10 centimetres per second, resulting in a vertical resolution of several metres for the velocity profile produced.

Acoustic and satellite sensing. Remote sensing of the ocean can be done by aircraft and Earth-orbiting satellites or by sending acoustic signals through it. These techniques all offer a more sweeping view of the ocean than can be provided by slow-moving ships and hence have become increasingly important in oceanographic research.

Satellite-borne radar altimeters have proved to be especially useful. A radar system of this type can determine the distance between the satellite and the sea surface to an accuracy of better than 10 centimetres by measuring the time it takes for a transmitted pulse of radio energy to travel to the surface and return. By combining such a precise distance measurement with information about the satellite's orbit, oceanographers are able to produce maps of sea-surface topography. Moreover, they can deduce the pressure field of the sea surface by combining the distance measurement with knowledge about the geoid. They can in turn extrapolate information about the general circulation of the upper stratum of the ocean from a synoptic view of the surface pressure field.

Use of radar altimeters

Another remote-sensing technique involves the use of satellite-borne infrared and microwave radiometers to measure radiant energy released from the surface of the ocean. Such measurements are used to determine sea-surface temperature. High-resolution, infrared images transmitted by polar-orbiting satellites have provided researchers with an effective means of monitoring wave features in ocean currents over a wide area, as, for example, long equatorial waves in the Pacific Ocean and time variations in the flow of the Gulf Stream between Florida and Cape Hatteras, North Carolina.

Acoustic techniques also have many applications in the study of the ocean, particularly of those subsurface processes and physical properties inaccessible to satellite observation. In one such technique, the temperature structure of a water column from a given point on the seafloor to the surface is studied using an inverted echo sounder. This instrument, which features both an acoustic transmitter and a receiver, measures the time taken by a pulse of sound to travel from the sea bottom to the surface and back again. In most cases, a change in the average temperature of the water column above the instrument causes a fluctuation in the time interval between the transmission and the reception of the acoustic signal.

Other acoustic techniques can be utilized to study ocean variables on a large scale. A method known as ocean acoustic tomography, for example, monitors the travel time of sound pulses with an array of echo-sounding systems. In general, the amount of data collected is directly proportional to the product of the number of transmitters and receivers, so that much information on averaged oceanic properties can be gathered within a short period of time at relatively low cost.

Ocean acoustic tomography

Collection of biological samples. Life at the bottom, benthos, is affected by the water column and by the sediment–water interface; the swimmers, or nekton, are influenced by the water that they come in contact with; and the floaters, or plankton—phytoplankton (plant forms) and zooplankton (animal forms)—are influenced by the water and the transfers that occur at the surface of the sea. Thus, in most cases, measurements and sampling of marine life is best done in concert with measurements of the physical and chemical properties of the ocean and the surface effects of the atmosphere.

As a consequence of the close interaction of sea life and its environment, marine biologists and biological oceanographers use most of the techniques mentioned above as well as some specialized techniques for biological sampling. Investigative techniques include the use of sampling devices, remote sensing of surface life-forms by satellite and aircraft, and in situ observation of plants and animals in direct interaction with their environment. The latter is becoming increasingly important as biologists recognize the fragility of organisms and the difficulty of obtaining representative samples. The absence of good sampling techniques means that even today little is known about the distribution, number, and life cycles of many of the important species of marine life.

Some of the most commonly used samplers are plankton nets and midwater trawls. Nets have a mesh size smaller than the plankton under investigation; trawls filter out only the larger forms. The smaller net sizes can be used only when the ship is either stopped or moving ahead

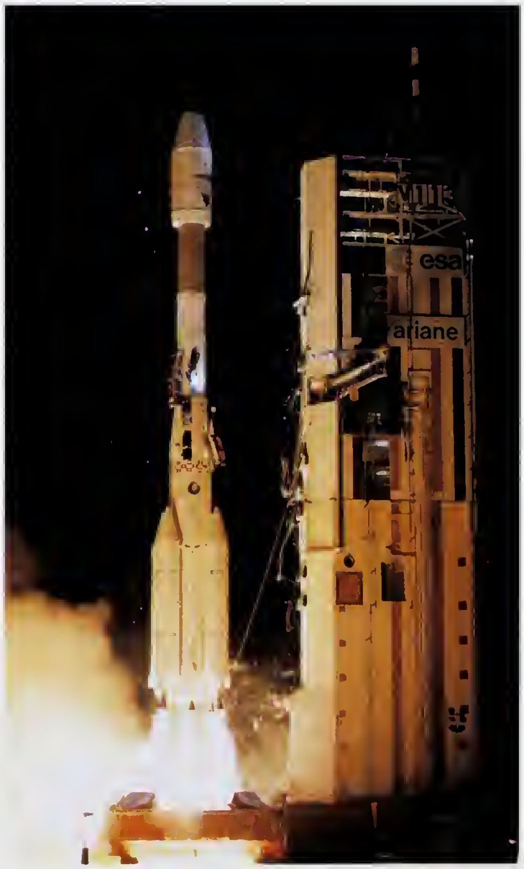
First-generation Meteosat satellite, developed by the European Space Agency. Placed in geostationary orbits near the prime meridian, Meteosats have provided daily weather data for Europe, Africa, and the eastern Atlantic Ocean. The first Meteosat was launched on November 23, 1977.



Ariane-44L launch vehicle with two commercial communications satellites aboard, lifting off on October 28, 1998, from the European Space Agency's Kourou space centre in French Guiana.

slowly; the larger can be used while the ship is travelling at normal speeds. Plankton nets can be used to sample at one or more depths. Qualitative samplers sieve organisms from the water without measuring the volume of water passing through, whereas quantitative samplers measure the volume and hence the concentration of organisms in a unit volume of seawater.

The Clark-Bumpus sampler is a quantitative type designed to take an uncontaminated sample from any desired depth while simultaneously estimating the filtered volume of seawater. It is equipped with a flow meter that monitors the volume of seawater that passes through the net. A shutter opens and closes on demand from the surface, admitting water and spinning the impeller of the meter while catching the plankton. When the impeller is stopped by closing the shutter, the sampler can be raised without contamination from plankton in the waters above.

The midwater trawl is specially designed for rapid collection at depths well below the surface and at such a speed that active, fast-swimming fish are unable to escape from the net once caught. Trawls can be towed at speeds up to nine kilometres per hour. To counteract the tendency of an ordinary net to surface behind the towing vessel, a midwater trawl of the Isaacs-Kidd variety uses an inclined-plane surface rigged in front of the net entrance to act as a depressor. The trawl is shaped like an asymmetrical cone with a pentagonal mouth opening and a round closed end. Within the net, additional netting is attached as lining. A steel ring is fastened at the end of the net to maintain shape. A large perforated can is fastened by drawstrings on the end of the net to retain the sample in relatively undamaged condition.

The use of acoustics to record and measure the distribution of biological organisms is becoming a widely adopted practice. Some organisms can be tracked directly by their distinctive sounds. By recording and analyzing these sounds, biologists are able to chart the behaviour and distribution of such life-forms.

Organisms that passively affect various electronic systems are large mammals, schools of fish, and plankton that either scatter sound and so appear as false targets or background reverberation, or that attenuate the acoustic signal. Some fishes and invertebrates make up layers of acoustic-scattering material, which may exhibit daily vertical movement related to daily changes in light.

Light in the upper layers of the ocean is crucial to maintaining marine life. The penetration and absorption of light and the colour and transparency of the ocean water are indicative of biological activity and of suspended material. In situ measurements of water transparency and absorption include the submarine photometer, the hydrophotometer, and the Secchi disk. The submarine photometer records directly to depths of about 150 metres the infrared, visible, and ultraviolet portions of the spectrum. The hydrophotometer has a self-contained light source that allows greater latitude in observation because it can be used at any time of night or day and measures finer gradations of transparency. The Secchi disk, designed to measure water transparency, is a circular white disk that is lowered on a cable into the sea. In practice, the depth at which it is barely visible is noted. The greater the depth reading, the more transparent is the water.

The primary productivity of the ocean, which occurs in the upper layers, can be monitored by continuous measurement of absorption by chlorophyll molecules. This occurs in the red and blue portions of the spectrum, leaving the green to represent the characteristic colour of biological activity. Satellite measurements of ocean colour that span a number of wavelengths in the visible and infrared portions of the spectrum are used to give a large-scale view of the biological activity and suspended material in the ocean.

Exploration of the seafloor and the Earth's crust. The ocean floor has the same general character as the land areas of the world: mountains, plains, channels, canyons, exposed rocks, and sediment-covered areas. The lack of weathering and erosion in most areas, however, allows geological processes to be seen more clearly on the seafloor than on land. Undisturbed sediments, for example, contain a historical record of past climates and the state of the ocean, which has enabled geologists to find a close relation between past climates and the variation of the distance of the Earth from the Sun (the Milankovich effect).

Because electromagnetic radiation cannot penetrate any significant distance into the sea, the oceanographer uses acoustic signals, explosives, and earthquakes, as well as gravity and magnetic fields, to probe the seafloor and the structure beneath. Such techniques—which now include the capability to produce a swath, or two-dimensional, description of the seafloor beneath a ship—are providing increasingly accurate data on the shape of the ocean, its roughness, and the structure beneath. Satellite techniques are a more recent development. Because the shape of the sea surface is closely related to that of the seafloor due to gravity, satellite measurements of surface topography have been used to provide a global view of the ocean bottom. They also have provided data for an accurate mapping of such features as seamounts.

Marine sedimentation

Research on marine sedimentation involves the study of deposition, composition, and classification of organic and inorganic materials found on the seafloor. Samples of such materials are thoroughly examined aboard research vessels or in shore-based laboratories, where investigators analyze the size and shape of constituent particles, determine chemical properties such as pH, and identify and categorize the minerals and organisms present. From thousands of reported classifications and collected samples, bottom-sediment charts are prepared.

Various kinds of equipment are used to obtain samples from the seafloor. These include grabbing devices, dredges, and coring devices.

Grabbing devices, commonly known as snappers, vary widely in size and design. One general class of such devices is the clamshell snapper, which is used to obtain small samples of the superficial layers of bottom sediments. Clamshell snappers come in two basic varieties. One measures 76 centimetres in length, weighs roughly 27 kilograms (one kilogram = 2.2 pounds), and is constructed of stainless steel. The jaws of this device are closed by heavy arms, which are actuated by a strong spring and lead weight. It is capable of trapping about a pint of bottom material. The second type of clamshell snapper is appreciably smaller. Commonly called the mud snapper, this device is approximately 28 centimetres long and weighs 1.4 kilograms. Other grabbing devices include the orange peel bucket sampler, which is used for collecting bottom materials in shallow waters. A small hook attached to the end of the lowering wire supports the sampler as it is lowered and also holds the jaws open. When contact is made with the bottom, the sampler jaws sink into the sediment and the wire tension is released, allowing the hook to swing free of the sampler. Upon hoisting, the wire takes a strain on the closing line, which closes the jaws and traps a sample. The underway bottom sampler, or scoopfish, is designed to sample rapidly without stopping the ship. It is lowered to depths less than 200 metres from a ship moving at speeds no more than 28 kilometres per hour. The sampler weighs five kilograms and can capture samples ranging from mud to coral.

The second major category of bottom sampler is the dredge, which is dragged along the seafloor to collect materials. Bottom-dredging operations require very sturdy gear, particularly when dredging for rock samples. A typical dredge is constructed of steel plate and is 30 centimetres deep, 60 centimetres wide, and 90 centimetres long. The forward end is open, but the aft end has a heavy grill of round steel bars that is designed to retain large rock samples. When finer sized material is sought, a screen of heavy hardware cloth is placed over the grill.

Coring devices

Coring devices typically have three principal components: interchangeable core tubes, a main body of streamlined lead weights, and a tailfin assembly that directs the corer in a vertical line to the ocean bottom. The amount of sediment collected depends on the length of the corer, the size of the main weight, and the penetrability of the bottom. One type of coring device, the lightweight Phleger corer, takes samples only of the upper layer of the ocean bottom to a depth of about one metre. Deeper cores are taken by the piston corer. In this device, a closely fitted piston attached to the end of the lowering cable is installed inside the coring tube. When the coring tube is driven into the ocean floor, friction exerts a downward pull on the core sample. The hydrostatic pressure on the ocean bottom, however, exerts an upward pressure on the core that will work against a vacuum being created between the piston and the top of the core. The piston, in effect, provides a suction that overcomes the frictional forces acting between the sediment sample and the inside of the coring tube. The complete assembly of a typical piston core weighs about 180 kilograms and can be used to obtain samples as long as 20 metres. An improved version of this device, the hydraulic piston corer, is used by deep-sea drilling ships such as the "JOIDES Resolution." Essentially undisturbed cores of lengths up to 200 metres have been obtained with this type of corer.

Investigators may also make use of wire-line logging tools that are capable of measuring electrical resistance, acoustic properties, and magnetic and gravitational effects in the holes drilled. The "JOIDES Resolution" is equipped with tools of this sort, including a remote television camera, which are lowered into a drill hole after the core has been removed. Such wire-line logging apparatus make data immediately available for scientific analysis and decision making.

Use of acoustic techniques for studying the seafloor

Acoustic techniques have reached a high level of sophistication for geological and geophysical studies. Such multifrequency techniques as those that employ Seabeam and Gloria (Geological Long-Range Inclined Asdic) permit mapping two-dimensional swaths with great accuracy from a single ship. These methods are widely used to ascertain the major features of the seafloor. The Gloria system, for example, can produce a picture of the morphology of a region at a rate of up to 1,000 square kilometres per hour. Techniques of this kind are employed in conjunction with seismic reflection techniques, which involve the use of multichannel receiving arrays to detect sound waves triggered by explosive shots (*e.g.*, dynamite blasts) that are reflected off of interfaces separating rocks of different physical properties. Such techniques make it possible to measure the structure of the Earth's crust deep below the seafloor. Figure 8 shows the geometry for two ships engaged in acoustic profiling of the terrestrial crust. The depth to which the crust can be surveyed corresponds roughly to the spacing between the ships—in this particular case, nearly 10 kilometres. (A.B.R./D.J.Ba.)

Space exploration

Humans have always looked at the heavens and wondered about the nature of the objects that they could see in the night sky. With the development of rockets and the advances in electronics and other technologies in the 20th century, it became possible to send machines and then people above Earth's atmosphere into outer space. Achieving spaceflight enabled humans to begin to explore the solar system and the rest of the universe, to understand the many objects and phenomena that are better observed from a space perspective, and to use for human benefit the resources and attributes of the space environment. All of these activities—discovery, scientific understanding, and the application of that understanding to serve human purposes—are elements of space exploration.

ELEMENTS OF SPACEFLIGHT

Definition of space

Space, as considered here, is defined as all the reaches of the universe beyond Earth's atmosphere. There is no definitive boundary above Earth at which space begins, but in terms of the limiting altitude for vehicles designed for atmospheric flight, it may be considered to be as low as 45 kilometres (28 miles). The lowest practical orbit for an artificial satellite around Earth is about 160 kilometres (100 miles).

The space that separates cosmic objects is not entirely empty. Throughout this void, matter is scattered at extremely low densities. Nevertheless, space constitutes a much greater vacuum than has been achieved on Earth. Additionally, space is permeated by gravitational and magnetic fields, a wide spectrum of electromagnetic radiation, and high-energy cosmic-ray particles.

Kinds of spacecraft. *Spacecraft* is a general term that includes sounding rockets, unmanned artificial satellites and space probes, space stations, and vehicles for carrying humans to and from space. With the exceptions of the sounding rocket and the space shuttle, spacecraft are considered separately from the rocket-powered vehicle that launches the spacecraft into orbit or boosts it away from Earth's vicinity. A space probe is an unmanned spacecraft that is given a velocity great enough to allow it to escape Earth's gravitational attraction. A deep-space probe is a probe sent beyond the Earth-Moon system; if sent to explore other planets, it is also called a planetary probe. A space station is an artificial structure placed in orbit and equipped to support human habitation for extended periods.

Spacecraft differ greatly in size, shape, complexity, and purpose. Lightness of weight and functional reliability are primary features of spacecraft design. Depending on their mission, spacecraft may spend minutes, days, months, or years in the environment of space. Mission functions must be performed while exposed to high vacuum, extreme variations in temperature, and strong radiation.

A general differentiation of spacecraft is by function—scientific or applications. A scientific satellite or probe carries instruments to obtain data on magnetic fields, space radiation, the Sun or other stars, planets and their moons, and other astronomical objects and phenomena. Applications spacecraft have utilitarian tasks; examples are Earth observation, military reconnaissance, telecommunications, and navigation and global positioning satellites.

Launching into space. *Gravity.* Earth's gravitational attraction was one of the major obstacles to spaceflight. Owing to the observations and calculations of earlier scientists, rocket pioneers understood Isaac Newton's laws of motion and other principles of spaceflight, but the application of those principles had to await the development of rocket power to launch a spacecraft to the altitude and velocity required for its mission.

A spacecraft and its launch vehicle are projected upward as a reaction to the high-speed jet of combustion gases produced by the vehicle's rocket engines. If, for example, the total lifting force, or thrust, of the engines is twice the weight of the entire spacecraft-vehicle assembly at liftoff, then the assembly will rise at an initial acceleration equal to the standard gravitational acceleration (abbreviated *g*) of 9.8 metres (32 feet) per second per second. As propellant mass is consumed and ejected from the rocket engines, the vehicle continually lightens and acceleration increases.

Change in gravity with altitude

Earth's gravitational pull on the rising spacecraft subsides slowly. At an altitude of 160 kilometres (100 miles), it is still 95 percent of that at Earth's surface, and at 2,700 kilometres (1,680 miles) it is 50 percent (4.9 metres per second per second). For the purpose of spaceflight, the gravitational pull of Earth becomes negligible only at distances of several million kilometres, except when a spacecraft approaches the Moon and lunar gravity (one-sixth that of Earth) becomes predominant.

Staging. Staging describes a technique in which two or more rocket systems are mounted in vertical sequence, forming a multistage launch vehicle. Initially, the lowest, or first, stage is ignited, and it (sometimes assisted by attached booster rockets) lifts the vehicle at increasing velocity until its propellants are exhausted. At that point the stage drops off, lightening the vehicle, and the second stage is ignited. This stage, which is smaller and of lower thrust, then accelerates the launch vehicle further. The use of additional stages generally follows the same pattern.

For some missions the final stage is not employed during the initial climb into space but reserved for a later step of the flight. For example, a spacecraft carried on a three-stage vehicle may use the first two stages to achieve a low "parking orbit" around Earth. It is then boosted to a higher orbit or away from Earth by the third stage.

Acceleration rates. In general, the longer it takes a space vehicle to leave Earth's atmosphere and achieve required velocity, the less economical the procedure becomes. At low accelerations the launch vehicle wastes great quantities of propellant because, in effect, it is investing nearly 10 metres per second of velocity cach second of travel just to counter Earth's gravitational acceleration. An upper limit of acceleration is governed by the maximum accelerative stress permissible upon the vehiclc structure and the maximum spacecraft payload. In manned spaceflight an acceleration about six times that of gravity (6 *g*) is considered the maximum tolerable when the human body is positioned perpendicular to thc acceleration force—*i.e.,* with the head and heart at the same level.

Maximum acceleration for humans

Flight trajectories. There are four general types of trajectories: sounding rocket, Earth orbit, Earth escapc, and planetary.

Sounding rocket. Sounding rockets provide the only means of making scientific measurements at altitudes of 45–160 kilometres (28–100 miles), betwecn the maximum altitude of balloons and the minimum altitude of orbiting satellites. They can be single-stage or multistage vchicles and are launched nearly vertically. After all of the rockct stages have expended their fuel and dropped away, the payload section continues to coast upward, slowly losing speed because of gravity. Upward velocity drops to zero at peak altitude, and the payload then begins to fall. Typically, the payload is retrieved by parachute and flown again. Prior to parachute deployment, the flight path follows a parabolic trajectory, and flight time is less than 30 minutes.

Earth orbit. Flight into Earth orbit is achieved by launching a rocket vertically and then tilting its trajectory so that its flight is parallel to Earth's surface at the time that its final stage reaches orbital velocity at the desircd altitude. At this precise point, the rocket engine is shut down. A spacecraft carried aboard the rocket is then in free fall about Earth, the centrifugal pull on the spacecraft being equal to Earth's pull of gravity. At an altitude of 200 kilometres (125 miles), the velocity required to orbit Earth is about 29,000 kilometres (18,000 miles) per hour. Because this altitude is above most of the atmosphere, aerodynamic drag is not great, and the spacecraft will continue to orbit for an extended time.

The time required for a satellite to make one complete revolution is called the orbital period. At 200 kilometres, this is about 90 minutes. As the altitude increases, the orbital velocity of a satellite decreases and the orbital period increases. For example, at an altitude of 1,730 kilometres (1,075 miles), the orbital velocity is 25,400 kilometres (15,780 miles) per hour, and the period is two hours.

Geostationary orbit

At about 35,800 kilometres (22,250 miles), a satellite's velocity is 11,100 kilometres (6,900 miles) per hour, and its orbital period has a special value. It is equal to a sidereal day, the rotational period of Earth measured against the fixed stars (about four minutes shorter than the conventional 24-hour solar day). A satellite in this orbit has properties desirable for certain applications. For example, if the orbit lies in the plane of Earth's Equator, the satellite appears to be stationary in the sky. This particular orbit, called a geostationary orbit, is used for communications and meteorological satellites.

All of the above figures assume a circular orbit, which for a satellite is often ideal but difficult to achieve. Usually a satellite's orbit is an ellipse with a perigee altitude (nearest distance to Earth) and an apogee altitude (farthest distance from Earth). If thrust is available, a satellite's orbit may be made more nearly circular by reducing the velocity at perigee (which lowers the apogee) or by increasing the velocity at apogee (which raises the perigee). Thrust in such instances is applied against or in the direction of flight, respectively.

In launching a satellite into Earth orbit, the launch vehicle most commonly is tilted after liftoff in an easterly direction. Launching to the east is done to take advantage of the velocity imparted to the vehicle by Earth's eastward rotation. This rotational surface velocity is about 1,670 kilometres (1,037 miles) per hour at the Equator and 1,470 kilometres (913 miles) per hour at the latitude of Cape Canaveral, Florida. At the higher latitude of Russia's Baikonur launch site in Kazakhstan, the surface velocity is 1,170 kilometres (727 miles) pcr hour. It would be possible to launch a satellitc into a westerly orbit, but additional velocity, and thus additional fuel expenditure, would be required to achieve an orbit of the same altitude compared with an easterly orbit.

Polar orbit

If the satellite is to be put into a polar orbit—an orbit that crosses over Earth's poles—it is launched in a northerly or southerly direction. Although the bcnefit of an eastcrly launch is lost, a satellite in an orbit pcrpcndicular to the Equator offers other advantages. As Earth turns on its axis, the satellite travels over all parts of the globc cvery fcw revolutions. Satcllitcs that monitor Earth's environmcnt, such as remote sensing satellites and some weather satcllites, use polar orbits.

Earth escape. In order to escapc completely from Earth's gravity, a spacecraft requires a launch vclocity of about 40,000 kilometres (25,000 miles) per hour. If it subsequently docs not come undcr thc gravitational influencc of anothcr cclestial body, it will go into an orbit about thc Sun like a tiny planetoid. With precisc timing, a spaccraft can be sent on a trajectory that will carry it ncar thc Moon. In thc casc of thc Apollo lunar landing flights, the spacecraft was placed on a trajectory calculated to pass ahead of the Moon and, under the influcnce of lunar gravity, to swing around thc far side. If no velocity-changing maneuver had been made, the spacccraft would have looped around the Moon and rcturned on a trajectory toward Earth. By reducing flight spccd on the Moon's far side, Apollo astronauts placed thcir craft in a lunar orbit held by lunar gravity.

The so-called three-body problem of celestial mechanics (in the case of the Apollo missions, the relativc motions of Earth, the spacecraft, and the Moon undcr their mutual gravitational influence) is extremely complcx and has no general solution. Although equations exprcssing the relative motions can be written for specific cascs, no expcdicnt approximate solutions were possible before the development of high-speed digital computcrs for calculating trajectories of long-range missiles. Computcrs intcgratc the complicated equations of motion numerically, show thc spacecraft's complete trajectory at succcssivc positions through space, and compare the actual flight path to the preplanned path at any point in time.

Planetary flights. Because of the elliptical nature of planetary orbits, distances vary between Earth and the other planets. In the case of Earth's nearest neighbours, Venus and Mars, a so-called favourable launch opportunity occurs about every two years. Flights can be made at other times, but the velocity required is greater and length of time is longer, or, for a given launch vehicle, the payload must be lighter in weight.

The trajectory from Earth to Venus or Mars can be planned to take advantage of the changing orbital rela-

Hohmann, or transfer, orbit

tionships of the planets for the most economical flight in terms of fuel and energy. Such advantageous paths, called Hohmann or transfer orbits, were described in the 1920s. Although these trajectories require the least velocity, they are of long duration—as long as 260 days to Mars, for example. Thus, a compromise trajectory is often used, as in the case of Mariners 6 and 7 in 1969. Launched on February 24, 1969, Mariner 6 passed within 3,430 kilometres (2,130 miles) of the planet 157 days later, when Mars was 92.8 million kilometres (57.7 million miles) from Earth.

Gravity-assist technique

Some trajectories use the fall into a planet's gravitational field to transfer momentum from the planet to the spacecraft, thereby increasing its velocity and altering its direction. This gravity-assist, or slingshot, technique has been used by numerous planetary probes. For example, the Galileo probe during its six-year voyage to Jupiter swung by Venus once and Earth twice in order to reach its ultimate target in 1995.

The same considerations for planetary trajectories apply to spacecraft destined for other objects in deep space, such as asteroids and comets. For instance, the flight path of the Near Earth Asteroid Rendezvous (NEAR) spacecraft, which reached the asteroid Eros in 2000, incorporated a trajectory-reshaping flyby of Earth.

Trajectory correction

Navigation, docking, and recovery. *Navigation.* Traveling from point A to point B in space is almost never in a straight line or at constant velocity because of the many influences on the body in motion. The basis for space navigation is inertial guidance—*i.e.,* guidance based on the inertia of a spinning gyroscope, irrespective of external forces and without reference to the Sun or stars. By the use of three gyroscopes and accelerometers, a spacecraft's navigation system can make precise measurements of any change in velocity, either positive or negative, along any or all of the three principal axes. By changing attitude (conducting rotation about one or more axes) and firing one or more thrust motors, a spacecraft can make corrections to its trajectory. Preprogrammed computers, both on the ground and in larger spacecraft, continually monitor where the spacecraft is, where it was, and where it is supposed to be going.

During the launch phase, corrections to deviations in the planned flight path are usually made at once by small thrust motors on the launch vehicle, by deflection of the rocket exhaust jet, or by swinging one or more of the rocket engines in a gimbal mount. In the case of a rendezvous and docking between two spacecraft, radar data inform a crew—or, in the case of automated maneuvers, a computer—of the corrections required along each axis. With the implementation of the satellite-based Navstar Global Positioning System in the 1980s, it became possible for spacecraft to verify their locations within a few metres and their speeds within a few metres per second.

Rendezvous and docking. Rendezvous is the process of bringing two spacecraft together, whereas docking is their subsequent meeting and physical joining. The essential elements of a rendezvous are the matching of orbital trajectories and the movement of one spacecraft within close proximity of the other, typically within 100 metres (330 feet). Ideally, the two spacecraft also should lie in the same orbital plane.

Ordinarily for a rendezvous mission, one spacecraft is already in orbit, and the second spacecraft is launched to meet it. To achieve rendezvous, the launch of the second craft is timed within a fraction of a second. Because the orbiting spacecraft already has a high velocity relative to the second spacecraft on the ground, the second craft is launched well before the first passes overhead. The aim is to establish a coplanar orbit just below the first spacecraft. In this configuration the second craft, being at a lower orbit, is traveling at a faster speed and will overtake the first. When it is slightly ahead of the first spacecraft, it fires thrusters in a way that causes it to rise in orbit and thus to slow down until it matches the first craft's orbital altitude and velocity. Radar systems and on-board computers are necessary for such operations.

First rendezvous in space

Gemini 6 and 7 in 1965 were the first spacecraft to perform a rendezvous. In the Apollo lunar landing missions, the ascent stage of the Lunar Module rose from the Moon's surface to rendezvous and dock with the orbiting Command Module. Russian Soyuz spacecraft and U.S. space shuttle orbiters have rendezvoused and docked routinely with space stations. Whereas the United States has relied on human crews for close rendezvóus and docking, Russian spacecraft can perform these maneuvers automatically using technology developed and refined in the Soviet space program.

Because of payload limitations, spacecraft beyond a certain size and complexity cannot be launched into Earth orbit at one time. Building a large structure such as the International Space Station or, similarly, a future spacecraft for a human trip to Mars requires reliable rendezvous and docking techniques that can be used to assemble component parts taken to orbit on separate launches. Furthermore, rotation of space crews and emergency rescue missions require rendezvous and docking capability.

Reentry and recovery. Reentry refers to the return of a spacecraft into Earth's atmosphere. The blanket of relatively dense gas surrounding Earth is useful as a braking, or retarding, force resulting from aerodynamic drag. A concomitant effect, however, is severe frictional heating caused by rapid flow of atmospheric gas molecules along the spacecraft's blunt forward profile. Initially, heat shields were made of ablative materials that carried away the heat of reentry as they were shed, but the space shuttle introduced refractory materials—silica tiles and a reinforced carbon-carbon material—that withstood the heat directly.

Angle of reentry

Inherent in the safe reentry of a spacecraft is precise control of the angle of reentry. This angle with respect to Earth's horizon is −6.2° and is held within limits of 1° in either direction. If the reentry angle is too shallow, the spacecraft will skip or bounce off the atmosphere and back into space. If the angle is too great, the heat shield will not survive the extreme heating rates nor the spacecraft the high forces of deceleration. Returning Apollo Command Modules approached Earth at nearly 40,000 kilometres (25,000 miles) per hour. Even with a satisfactory reentry angle, the capsules' heat shields were subjected to temperatures approaching 3,000° C (5,400° F).

During the final phases of descent, a spacecraft typically deploys parachutes, which lower the vehicle to a soft landing. The Apollo Command Modules employed this technique to make ocean splashdowns. Russian Soyuz spacecraft traditionally soft-land on the ground. The reentry procedure of the winged space shuttle orbiter differs markedly: it descends by gliding and lands on a runway like an ordinary airplane. (F.C.D. III/Da.D./Ed.)

PRELUDE TO SPACEFLIGHT

From ancient times, people around the world have studied the heavens and used their observations and explanations of astronomical phenomena for both religious and practical purposes. Some even dreamed of leaving Earth to explore other worlds. In order to translate these visions of space travel into reality, it was necessary to devise some practical means of countering the influence of Earth's gravity. By the beginning of the 20th century, the centuries-old technology of rockets had advanced to the point at which it was reasonable to consider their use to accelerate objects to a velocity sufficient to enter orbit around Earth or even to escape Earth's gravity and travel away from the planet.

Pioneers in rocketry. *Tsiolkovsky.* The first person to study in detail the use of rockets for spaceflight was the Russian schoolteacher and mathematician Konstantin Tsiolkovsky. In 1903 his article "Exploration of Cosmic Space by Means of Reaction Devices" laid out many of the principles of spaceflight. Up to his death in 1935, Tsiolkovsky continued to publish sophisticated studies on the theoretical aspects of spaceflight. He never complemented his writings with practical experiments in rocketry, but his work greatly influenced later space and rocket research in the Soviet Union and Europe.

Goddard. In the United States, Robert Goddard became interested in space exploration after reading works such as H.G. Wells's *The War of the Worlds* (1898). He received his first two patents for rocket technology in 1914, and, with funding from the Smithsonian Institution, he published a theoretical treatise, *A Method of Reaching Ex-*

treme Altitudes, in 1919. Goddard's claim that rockets could be used to send objects as far as the Moon was widely ridiculed in the public press. Thereafter, the already shy Goddard conducted much of his work in secret, preferring to patent rather than publish his results. This approach limited his influence on the development of American rocketry, although early rocket developers in Germany took notice of his work.

Goddard's first rocket launch

In the 1920s, as a professor of physics at Clark University in Worcester, Massachusetts, Goddard began to experiment with liquid-fueled rockets. His first rocket, launched in Auburn, Massachusetts, on March 16, 1926, rose 12.5 metres (41 feet) and traveled 56 metres (184 feet) from its launching place. The noisy character of his experiments made it difficult for Goddard to continue work in Massachusetts. With support from aviator Charles Lindbergh and financial assistance from the philanthropic Daniel Guggenheim Fund for the Promotion of Aeronautics, he moved to Roswell, New Mexico, where from 1930 to 1941 he built engines and launched rockets of increasing complexity.

Oberth. The third widely recognized pioneer of rocketry, Hermann Oberth, was by birth a Romanian but by nationality a German. Reading Jules Verne's *From the Earth to the Moon* (1865) as a youth inspired him to study the requirements for interplanetary travel. Oberth's 1922 doctoral dissertation on rocket-powered flight was rejected by the University of Heidelberg for being too speculative, but it became the basis for his classic 1923 book, *Die Rakete zu den Planetenräumen* ("The Rocket into Interplanetary Space"). The work explained the mathematical theory of rocketry, applied the theory to rocket design, and discussed the possibility of constructing space stations and of traveling to other planets.

In 1929 Oberth published a second influential book, *Wege Zur Raumschiffahrt* (*Ways to Spaceflight*). His works led to the creation of a number of rocket clubs in Germany, as enthusiasts tried to turn Oberth's ideas into practical devices. The most important of these groups historically was the Verein für Raumschiffahrt (VfR; "Society for Spaceship Travel"), which had as a member the young Wernher von Braun. Although his work was crucial in stimulating the development of rocketry in Germany, Oberth himself had only a limited role in that development. Alone among the rocket pioneers, Oberth lived to see his ideas become reality: he was Braun's guest at the July 16, 1969, launch of Apollo 11.

Early rocket development. *Germany.* It was space exploration that motivated the members of the German VfR to build their rockets, but in the early 1930s their work came to the attention of the German military. In 1932, Braun, at age 20, became chief engineer of a rocket development team for the German army. After Adolf Hitler came to power in 1933, Braun was named the civilian head of that team, under the military command of Walter Dornberger. To give Braun's engineers the needed space and secrecy for their work, the German government erected a development and test centre at Peenemünde on the coast of the Baltic Sea. There they developed, among other devices, the V-2 ballistic missile. Although built as a weapon of war, the V-2 later served as the predecessor of many of the rockets used in the early space programs of the United States and the Soviet Union.

Role of V-2 in early space programs

As World War II neared its end in early 1945, Braun and many of his associates chose to surrender to the United States, where they believed they would likely receive support for their rocket research and space exploration plans. Later in the year they were brought to the United States, as were their engineering plans and the parts needed to construct a number of V-2s. The German rocket team played a central role in the early development of space launchers for the United States.

United States. In 1936, as Braun was developing rockets for the German military, several young American engineers led by graduate student Frank Malina began working on rocketry at the Guggenheim Aeronautical Laboratory of the California Institute of Technology (GALCIT). In 1943 Malina and his associates began calling their group the Jet Propulsion Laboratory (JPL), a name that was formally adopted the following year. JPL soon became a centre for missile research and development for the U.S. Army. Following World War II those weapons were adapted for use in early U.S. space experiments. After 1958, when it became part of the newly established National Aeronautics and Space Administration (NASA), JPL adapted itself to be the leading U.S. centre for solar system exploration.

Soviet Union. In the U.S.S.R., the government took an interest in rockets as early as 1921 with the founding of a military facility devoted to rocket research. Over the next decade that centre was expanded and renamed the Gas Dynamics Laboratory. There in the early 1930s Valentin Glushko carried out pioneering work on rocket engines. Meanwhile, other rocket enthusiasts in the Soviet Union organized into societies that by 1931 had consolidated into an organization known as GIRD (the abbreviation in Russian for "Group for the Study of Reactive Motion"), with branches in Moscow and Leningrad. Emerging as a leader of the Moscow branch was the aeronautical engineer Sergey Korolyov, who had become interested in spaceflight at a young age. Korolyov and a colleague, Mikhail Tikhonravov, on August 17, 1933, launched the first Soviet liquid-fueled rocket. Later that year, the Moscow and Leningrad branches of GIRD were combined with the Gas Dynamics Laboratory to form the military-controlled Rocket Propulsion Research Institute (RNII), which five years later became Scientific-Research Institute 3 (NII-3). In its early years the organization did not work directly on space technology, but ultimately it played a central role in Soviet rocket development.

Launch of first Soviet liquid-fueled rocket

Korolyov was arrested in 1937 as part of the Soviet leader Joseph Stalin's great purges of intellectuals and sent to a Siberian prison. After Stalin recognized the imprudence of removing the best technical people from the Soviet war effort, Korolyov was transferred to a prison-based design bureau, where he spent most of World War II working on weapons, although not on large rockets. By the end of the war Stalin had become interested in ballistic missiles, and he sent a team, which included Korolyov, on visits to Germany to investigate the V-2 program. A number of German engineers were relocated to the Soviet Union in the aftermath of the war, but they did not play a central role in postwar Soviet rocket development.

ON THE BRINK OF SPACE

Between 1946 and 1951 the U.S. Army conducted test firings of captured German V-2 rockets at White Sands, New Mexico. These sounding-rocket flights reached high altitudes (120–200 kilometres [75–125 miles]) before falling back to Earth. Although the primary purpose of the tests was to advance rocket technology, the Army invited American scientists interested in high-altitude research to put experiments aboard the V-2s. An Upper Atmosphere Research Panel, chaired by the physicist James Van Allen, was formed to coordinate the scientific use of these rocket launchings. The panel had a central role in the early years of U.S. space science, which focused on experiments on solar and stellar ultraviolet radiation, the aurora, and the nature of the upper atmosphere. As the supply of V-2s dwindled, other U.S.-built sounding rockets such as the WAC Corporal, Aerobee, and Viking were put into use. In other countries, particularly the Soviet Union, rocket-based upper-atmosphere research also took place after World War II.

In the early 1950s, scientists began planning a coordinated international investigation of Earth, to be called the International Geophysical Year (IGY), that would be held in 1957–58 under the auspices of the International Council of Scientific Unions. By this time progress in rocket development had advanced such that orbiting of an artificial satellite around Earth by 1957 seemed feasible. At the urging of American scientists, IGY planners in 1954 called for scientifically instrumented satellites to be launched as part of IGY activities. Soon thereafter, the governments of the Soviet Union and the United States governments each announced plans to do so.

In the years following World War II, the United States and the U.S.S.R. became political and military competitors in what soon was being called the Cold War. Because the Soviet Union was a closed society, U.S. leaders gave high priority to developing technology that could help gather intelligence on military preparations within the Soviet borders. As orbiting satellites neared realization, the idea of equipping such satellites with cameras and flying them over Soviet territory became more attractive to U.S. planners, and the U.S. Air Force began work on a reconnaissance satellite project.

FROM SPUTNIK TO APOLLO

Sputnik 1

The first satellites. Although Soviet plans to orbit a satellite during the IGY had been discussed extensively in technical circles, the October 4, 1957, launch of Sputnik 1 came as a surprise, and even a shock, to most people. Prior to the launch, skepticism had been widespread that the U.S.S.R. possessed the technical capabilities to develop both a sophisticated scientific satellite and a rocket powerful enough to put it into orbit. Under Korolyov's direction, however, the Soviet Union had been building an intercontinental ballistic missile (ICBM), with engines designed by Glushko, that was capable of delivering a heavy nuclear warhead to American targets. That ICBM, called the R-7 or Semyorka ("Number 7"), was first successfully tested on August 21, 1957, which cleared the way for its use to launch a satellite. Fearing that development of the elaborate scientific satellite intended as the Soviet IGY contribution would keep the U.S.S.R. from being the first into space, Korolyov and his associates, particularly Tikhonravov, designed a much simpler 83.6-kilogram (184-pound) sphere carrying only two radio transmitters and four antennas. After the success of the R-7 in August, that satellite was rushed into production and became Sputnik 1. A second, larger satellite carrying scientific instruments and the dog Laika, the first living creature in orbit, was launched November 3. The even larger, instrumented spacecraft originally intended to be the first Soviet satellite went into orbit in May 1958 as Sputnik 3.

After President Dwight Eisenhower in May 1955 had committed the United States to an IGY satellite, the mission was assigned to the Naval Research Laboratory, rather than to the Army's Redstone Arsenal, where Braun worked, so that the work would not interfere with Redstone's higher-priority development of ballistic missiles. The Navy project, called Vanguard, would use a new launch vehicle based on modified sounding rockets to orbit a small scientific satellite. Vanguard made slow progress over the subsequent two years, but after Sputnik's success, the White House pressed to have the satellite launched as quickly as possible.

Explorer 1

Braun and his Army superiors had not agreed with the decision to assign the satellite mission to the Navy. After the launches of the first two Sputniks, they secured permission to attempt their own satellite launch. In anticipation of such a situation, they had kept in touch with JPL and Van Allen and so were able to prepare a satellite quickly. On January 31, 1958, Braun's Jupiter-C launch vehicle, a modified Redstone ballistic missile, carried into orbit Explorer 1, the first U.S. satellite. Designed at JPL, Explorer 1 carried Van Allen's experiment to measure cosmic rays. The results from this experiment and similar ones aboard other U.S. and Soviet satellites launched that same year revealed that Earth was surrounded by two zones of trapped particles, now known as the Van Allen radiation belts.

Corona reconnaissance satellites

Initial satellite launches were scientific in character, but U.S. government interest in reconnaissance satellites persisted. In February 1958, President Eisenhower authorized the development, under conditions of great secrecy, of such a spacecraft. The project, which came to be called Corona, would take pictures over the Soviet Union and return them to Earth by dropping the exposed film in a capsule that would be snatched out of the air as it parachuted back from space. After 12 failures, the first successful Corona mission took place on August 18, 1960; the returned film contained images of many previously unknown Soviet airfields and missile sites.

NASA

Development of space organizations. *United States.* As part of its response to the first Sputnik launches, the United States government debated how best to organize itself for its space activities. In February 1958 President Eisenhower created the Defense Advanced Research Projects Agency (DARPA) and assigned it responsibility for all U.S. space projects. Soon afterward, he decided to separate civilian from military space efforts and proposed the creation of a National Aeronautics and Space Administration to manage the civilian segment. After approval by Congress, NASA began operation on October 1, 1958. DARPA was not successful in establishing itself as a military space agency. By 1960, after the Army had been obliged to relinquish control of JPL and Braun's rocket team to NASA management, the U.S. Air Force had emerged as the leading military service for space.

Eisenhower also decided to create a separate organization to manage the secret reconnaissance satellite program. This effort resulted in the National Reconnaissance Office (NRO), jointly directed by the Department of Defense and the Central Intelligence Agency. The very existence of this organization was kept secret until 1992. The NRO operated the initial Corona program until 1972. It continued to manage the development of successor photointelligence satellite systems of increasing technological sophistication and also developed radar-surveillance and electronic-signals-collection satellites. All were operated under conditions of the highest secrecy.

After it received its mandate to send Americans to the Moon, NASA grew into a large organization. At the peak of the Apollo program, the agency had 34,000 employees; by the end of the 20th century, this labour force had shrunk to 19,000, but NASA remained by far the largest space agency in the world.

The U.S. Air Force had no separate organization for space until 1982, when the Air Force Space Command was created to manage its military space operations, which involved the use of satellites for meteorology, communication, navigation, and early warning of missile attack. The other U.S. military services soon created similar organizations to administer their smaller space activities. In 1985 these organizations were brought under a unified U.S. Space Command, dominated by the Air Force, which was responsible for 85 percent of military space activities.

Soviet Union. In contrast to the United States, the Soviet Union had no separate, publicly acknowledged space agency. For 35 years after Sputnik, various design bureaus—state-controlled organizations that actually conceived and developed aircraft and space systems—had great influence within the Soviet system. Rivalry among those bureaus and their heads, who were known as chief designers, was a constant reality and posed an obstacle to a coherent Soviet space program. Space policy decisions were made by the Politburo of the Central Committee of the Communist Party as well as the Soviet government's Council of Ministers. After 1965, the government's Ministry of General Machine Building was assigned responsibility for managing all Soviet space and missile programs; the Ministry of Defense was also quite influential in shaping space efforts. A separate military branch, the Strategic Missile Forces, was in charge of space launchers and strategic missiles. Various institutes of the Soviet Academy of Sciences, particularly the Institute for Space Research (IKI), proposed and managed scientific missions.

Russian Space Agency

Only after the dissolution of the U.S.S.R did Russia create a civilian organization for space activities. Formed in February 1992, the Russian Space Agency acted as a central focus for the country's space policy and programs. Although it began as a small organization, it quickly took on increasing responsibility for the management of nonmilitary space activities and, as an added charge, aviation efforts. It later was renamed the Russian Aviation and Space Agency.

Europe. In 1961, within four years of the launch of the first U.S. and Soviet satellites, the government of France created the French Space Agency (CNES), which grew to become the largest national organization of its kind in Europe. Gradually other European countries formed government or government-sponsored organizations for space, among them the German Aerospace Center (DLR), the British National Space Centre (BNSC), and the Italian

Space Agency (ASI). Still others included space as part of their science or technology ministries.

European Space Agency

In 1964, a European Space Research Organisation (ESRO), created at the initiative of European scientists to pool government resources in support of space science, began operations. Ten Western European countries and Australia joined the organization. In the same year, a parallel European Launcher Development Organisation (ELDO), which had seven European member states, was established to develop a space launch vehicle for Europe. In 1975, a new European Space Agency (ESA) was formed from ESRO and ELDO to carry out both of their tasks. At the beginning of the 21st century, ESA had 15 member states—Austria, Belgium, Denmark, Finland, France, Germany, Ireland, Italy, Norway, The Netherlands, Portugal, Spain, Sweden, Switzerland, and the United Kingdom. Canada also participated in some ESA projects. With a budget that made it the world's second largest civilian space agency, ESA carried out a comprehensive program in space science, applications, and infrastructure development.

Japan. In Japan, the University of Tokyo created an Institute of Space and Astronautical Science (ISAS) in 1964. This small group undertook the development of scientific spacecraft and the vehicles needed to launch them, and it launched Japan's first satellite, Ōsumi, in 1970. In 1981, oversight of ISAS was transferred to the Japanese Ministry of Education. In 1969, the Japanese government founded a National Space Development Agency (NASDA), which subsequently undertook a comprehensive program of space technology and satellite development and built a large launch vehicle, called the H-II, for those satellites. In 2001, both ISAS and NASDA came under the control of the Japanese Ministry of Education, Culture, Sports, Science and Technology.

Chinese rocket development

China. China's space program evolved largely in secret, under the joint control of the Chinese military and the Commission on Science, Technology, and Industry for the National Defense. The rocket engineer Qian Xuesen (Tsien Hsue-shen), who had worked at GALCIT in the 1940s and helped found JPL, returned to China after the Communist takeover of 1949, where he became the guiding figure in the development of Chinese missiles and launch vehicles, both originally derived from a Soviet ICBM. China developed a family of Long March boosters, which are used domestically and serve as competitors in the international commercial space launch market. Its space development has concentrated on applications such as communications satellites and Earth observation satellites for civilian and military use, and it has announced plans to initiate its own manned spaceflight program.

The first human spaceflights. During the 1950s, space planners in both the Soviet Union and the United States anticipated the launching of a human being into orbit as soon as the required launch vehicle and spacecraft could be developed and tested. Much of the initial thinking focused on some form of piloted space plane, which, after being launched atop a rocket, could maneuver in orbit and then return to Earth, gliding to a horizontal landing.

Ballistic capsule approach

Rather than base their human spaceflight programs on space planes, however, the Soviet Union and the United States, in their desire to put people into space as quickly as possible, opted for a less technically demanding ballistic approach. A person would ride in a capsule-like spacecraft atop a rocket to achieve orbit. At the end of the flight, another rocket (called a retro-rocket) would slow down the spacecraft enough for it to fall back to Earth on a ballistic trajectory. To accomplish this feat, the spacecraft would have to survive the intense heat caused by reentering the atmosphere at a high speed and then carry its passenger safely back to Earth's surface.

Vostok. Soon after the success of the first Sputniks, Korolyov and his associate Tikhonravov began work on the design of an orbital spacecraft that could be used for two purposes. One was to conduct photoreconnaissance missions and then return the exposed film to Earth. The other was to serve as a vehicle for the first human spaceflight missions. The spacecraft was known as Object K, but it was called Vostok when it was used to carry a human into space. Vostok had two sections—a spherical capsule in which the person would ride and a conical module that contained the instruments needed for its flight. The spacecraft was large for the time, weighing 4.73 metric tons. Vostok was designed so that the human aboard need not touch any control from launch to touchdown—he would be essentially just a passenger. Nor would he land with the spacecraft. Rather, he would be ejected from it at an altitude of seven kilometres (4.3 miles) and parachute to dry land, while the spacecraft landed nearby with its own parachutes.

Gagarin's historic spaceflight

After a series of five test flights carrying dogs and human dummies, the first human lifted into space in Vostok 1 atop a modified R-7 rocket on April 12, 1961, from the Soviet launch site at the Baikonur Cosmodrome in Kazakhstan. The passenger, Yury Gagarin, who was by that time being called a cosmonaut, was a 27-year-old Russian test pilot. After firing of the retro-rocket 78 minutes into the mission, the crew capsule separated from the instrument module—although not without problems—and Gagarin parachuted to a soft landing 108 minutes after his launch.

There were five additional one-person Vostok missions. In August 1961, Gherman Titov at age 25 (still as of 2001 the youngest person ever to fly in space) completed 17 orbits of Earth in Vostok 2. He became ill with space sickness (the equivalent of motion sickness on Earth) during the flight, an incident that caused a one-year delay in Vostok flights while Soviet physicians investigated the possibility that humans could not survive for extended times in the space environment. In August 1962, two Vostoks, 3 and 4, were orbited at the same time and came within 6.5 kilometres (four miles) of one another. This dual mission was repeatcd in June 1963; aboard the Vostok 6 spacecraft was Valentina Tereshkova, the first woman to fly in space.

Mercury. The initial U.S. effort to launch a human into space was known as Projcct Mercury. It was carried out by NASA, which had been given that responsibility ovcr Air Force objections. NASA engineers, led by Robert Gilruth and Maxime Faget, designed a small cone-shaped capsule for the mission. Compared with thc ncarly fivc-mctric-ton Vostok, it weighed 1.94 metric tons. Unlike the Soviet approach, in which a cosmonaut was orbited on the first human spaceflight, NASA planned several precautionary suborbital test flights in which an astronaut would bc in space only for a few minutes of his 15-minute up-and-down ride. The Mercury capsule would parachute with its passenger all the way back to Earth's surface, to land in the ocean and be recovered by Navy ships. Also in contrast to Vostok, the Mercury capsule was designed to allow the astronaut to control some aspccts of its flight whilc in spacc.

First U.S. orbital flights

The United States used chimpanzees, rather than dogs, as test subjects prior to human flights. On May 5, 1961, Alan Shepard made thc first manned Mercury flight atop a Redstone rocket. A second suborbital Mercury mission carrying Virgil Grissom followed in July. John Glenn became the first American astronaut to orbit Earth in his three-orbit mission on February 20, 1962. His Mercury spacecraft was launched by a modified Air Force Atlas ICBM. Three more one-man Mercury orbital flights, carrying astronauts Scott Carpenter, Walter Schirra, and L. Gordon Cooper, were conducted, the last being a 22-orbit mission in May 1963.

Gemini and Voskhod. In 1961, President John F. Kcnnedy announced that the United States would send people to the Moon "before this decade is out." In order to test many of the techniques that would be needed to carry out a lunar mission, particularly rendezvousing and docking two objects in space, the United States in late 1961 decided to develop a two-person spacecraft called Gemini. The Gemini spacecraft was much more complex than the rudimentary Mercury capsule and, at 3.81 metric tons, was twice as heavy. Another converted Air Force ICBM, a Titan II, was used to launch the Gemini spacecraft.

The first manned Gemini mission lifted into space in March 1965; nine more missions followed, the last in November 1966. On the second mission in June 1965, Edward White became the first American astronaut to operate outside a spacecraft. His 20-minute space walk—also known as extravehicular activity (EVA)—was without incident.

Although problems developed on many of the Gemini flights, the program demonstrated that people could live and work in space for as long as 14 days, more than the time needed for a round trip to the Moon. It also showed that astronauts could carry out rendezvous in space and could make useful observations of Earth.

As plans in the United States for multiple astronaut missions became known, the Soviet Union worked to maintain its lead in the space race by modifying the Vostok spacecraft so that it could carry as many as three persons. Korolyov could accomplish this only by having the crew fly without wearing spacesuits. The redesigned spacecraft was known as Voskhod. There were two Voskhod missions, one with three people aboard in October 1964 and another with a two-man crew in March 1965. On the second mission, cosmonaut Aleksey Leonov became the first human to leave an orbiting spacecraft, less than three months before White. His 12-minute EVA was full of problems, and his reentry of the Voskhod spacecraft was particularly difficult.

Soyuz. Korolyov and his associates began work in 1962 on a second-generation spacecraft, to be called Soyuz. It was to be a much more complex vehicle than Vostok, holding as many as three people in an orbital crew compartment, with a separate module for crew reentry and a third section containing spacecraft equipment and rocket engines for in-orbit and reentry maneuvers. Soyuz was to be capable not only of flights in Earth orbit but also, in modified versions, of flights around the Moon and even a lunar landing.

The first launch of Soyuz, with a single cosmonaut aboard, Vladimir Komarov, aboard, took place on April 23, 1967. Once the spacecraft reached orbit, it suffered a number of problems, which prompted ground controllers to bring Komarov back to Earth as soon as possible. After reentry, however, the spacecraft's main parachute did not fully deploy, and the Soyuz hit the ground at high speed. Komarov became the first person to perish during a spaceflight, and the accident dealt a major blow to Soviet hopes of orbiting or landing on the Moon before the United States.

First death during a spaceflight

After the problems with the Soyuz design were diagnosed and remedied, various models of the spacecraft served as the means of access to space for the Soviet, and then Russian, program of human spaceflight for more than 30 years. At the start of the 21st century, a version of Soyuz was used as the crew rescue vehicle—the lifeboat—for the early phase of construction and occupancy of the International Space Station.

The race to the Moon. *The American commitment.* In the immediate aftermath of Gagarin's orbital flight, President Kennedy was advised of Braun's belief that the Soviet Union, using Korolyov's existing R-7 launcher, could well succeed in sending a multiperson spacecraft into Earth orbit and perhaps even around the Moon before the United States. The first competition that the United States had a good chance of winning would be that of a manned lunar landing, because it would require each country to develop a new, more powerful rocket. On those technical grounds, and because a lunar landing would be a very visible demonstration of American strength, Kennedy announced on May 25, 1961, that the United States would commit itself to a lunar landing before 1970.

In response to Kennedy's decision, the United States carried out a warlike, but peaceful, mobilization of financial and human resources. NASA's budget was increased almost 500 percent in three years, and at its peak the lunar landing program involved more than 34,000 NASA employees and 375,000 employees of industrial and university contractors.

Elements of Apollo program

By the end of 1962 the basic elements of what was called Project Apollo were in place (see Figure 9). The launch vehicle would be a powerful Saturn V rocket, 110.6 metres (363 feet) tall and power driven by five huge engines generating a total of 33,000 kilonewtons (7.5 million pounds) of lifting power at takeoff—100 times the takeoff thrust of the Redstone rocket that had launched Shepard. After an intense debate, NASA chose a spacecraft configuration for Apollo that could be sent up in one launch, rather than a larger spacecraft that would need to be assembled in a series of rendezvous in Earth orbit. The Apollo spacecraft would have three sections. A Command Module would house the three-person crew on liftoff and landing and during the trip to and from the Moon. A Service Module would carry various equipment and the rocket engine needed to guide the spacecraft into lunar orbit and then send it back to Earth. A Lunar Module, comprising a descent stage and an ascent stage, would carry two people from lunar orbit to the Moon's surface and back to the Command Module. The ability of the Lunar Module's ascent stage to rendezvous and dock in lunar orbit with the Command Module after takeoff from the Moon was critical to the success of the mission.

The Soviet response. While committing the United States to winning the Moon race, President Kennedy also made several attempts in the early 1960s to convince the Soviet leadership that a cooperative lunar landing program between their two countries would be a better alternative. No positive reply from the Soviet Union was forthcoming, however. In fact, between 1961 and 1963 there was still vigorous debate within the Soviet Union over the wisdom of undertaking a lunar program, and no final decision had been made on the question.

Meanwhile, the separate Soviet design bureaus headed by Korolyov and Vladimir Chelomey competed fiercely for a lunar mission assignment, either a flight around the Moon or an actual landing. Finally, in August 1964, Korolyov received the lunar landing assignment, and, soon afterward, Chelomey was given responsibility for planning a circumlunar flight to be carried out before the 50th anniversary of the Bolshevik Revolution, which would take place in October 1967. In 1965, Soviet leaders decided to combine the efforts of the two rivals for the circumlunar mission, using a version of Korolyov's Soyuz spacecraft and a new rocket, the UR-500 (also called the Proton), designed by Chelomey.

Soviet manned lunar program

The rocket that Korolyov designed for the lunar landing effort was called the N1. Like the Saturn V, it was huge, standing 112.8 metres (370 feet) tall and having a planned takeoff thrust of 44,500 kilonewtons (10 million pounds). Instead of a few large rocket engines in its first stage, however, the N1 had 30 smaller engines. These were developed by Nikolay Kuznetsov, an aircraft-engine chief designer who had little experience with rocket engines, rather than the more capable Glushko. Korolyov and Glushko, already personal adversaries for many years, had disagreed on the proper fuel for the N1, and they finally decided that they could no longer work together.

Indecision, inefficiencies, inadequate budgets, and personal and organizational rivalries in the Soviet system thus posed major obstacles to success in the race to the Moon. To this was added the unexpected death on January 14, 1966, of Korolyov, at age 59, during surgery. His successor, Vasily Mishin, attempted to maintain the program's momentum, but he was not the effective manager or politically sophisticated operator that Korolyov had been.

Interim developments. In the United States, Apollo moved forward as a high-priority program. A major setback occurred on January 27, 1967, when astronauts Grissom, White, and Roger Chaffee were killed after their Apollo 1 Command Module caught fire during a ground test. The first manned Apollo mission, designated Apollo 7 and intended to test the redesigned Command Module, was launched into Earth orbit on October 11, 1968. The launcher used was a Saturn IB, a less-powerful rocket than the Saturn V needed to reach the Moon. The mission's success cleared the way for a bold step—the first launch of a crew atop a Saturn V to the lunar vicinity. On December 21, 1968, the Apollo 8 Command and Service modules, carrying astronauts Frank Borman, James Lovell, and William Anders, were put on a trajectory that sent them into orbit around the Moon on Christmas Eve, December 24.

First manned circumlunar voyage

One reason for conducting the Apollo 8 mission was to allow NASA to test most of the systems needed for a lunar landing attempt while waiting to carry out a manned trial in Earth orbit of the Lunar Module, whose development was behind schedule. Another was the concern that the Soviet Union would beat the United States in sending people

to the lunar vicinity. A circumlunar mission indeed had been part of Soviet plans, but the Soyuz 1 accident had made the October 1967 deadline infeasible. During 1968, a number of test flights of a circumlunar mission were made using the Proton launcher and a version of the Soyuz spacecraft designated Zond. In September Zond 5 carried a biological payload, including two tortoises, around the Moon and safely back to Earth, but two months later the Zond 6 spacecraft depressurized and then crashed on landing, ending any hope for a quick follow-on launch with a human crew.

Failure of Soviet Moon rocket

The Soviet lunar landing program went forward rather fitfully after 1964. The missions were intended to employ the N1 launch vehicle and another variation of the Soyuz spacecraft, designated L3, that included a lunar landing module designed for one cosmonaut. Although an L3 spacecraft was constructed and three cosmonauts trained for its use, the N1 rocket was never successfully launched. After four failed attempts between 1969 and 1972, the N1 program was finally cancelled in May 1974, thus ending Soviet hopes for human missions to the Moon.

The Apollo lunar landings and Apollo-Soyuz. By contrast with the Soviet lunar landing efforts, during 1969 all went well for the Apollo program. In March the Apollo 9 crew successfully tested the Lunar Module in Earth orbit, and in May the Apollo 10 crew carried out a full dress rehearsal for the landing, coming within 15,200 metres (50,000 feet) of the lunar surface. On July 16, 1969, astronauts Neil Armstrong, Edwin ("Buzz") Aldrin, and Michael Collins set off on the Apollo 11 mission, the first lunar landing attempt. While Collins remained in lunar orbit in the Command Module, Armstrong piloted the Lunar Module, nicknamed Eagle, away from boulders on the lunar surface and to a successful landing on a flat lava plain called the Sea of Tranquillity at 4:18 PM U.S. Eastern Daylight Time on July 20. Six and a half hours later, Armstrong, soon followed by Aldrin, left the Lunar Module and took the first human step on the surface of another celestial body. As he did so, he noted, "That's one small step for [a] man, one giant leap for mankind." (In the excitement of the moment, Armstrong skipped the "a" in the statement he had prepared.) Concluding 2.5 hours of activity on the lunar surface, the two men returned to the Lunar Module with 21.7 kilograms (47.8 pounds) of lunar samples. Twelve hours later they blasted off the Moon in the Lunar Module's ascent stage and rejoined Collins in the Command Module. The crew returned to Earth on July 24, splashing down in the Pacific Ocean.

Humans on the Moon

The successful Apollo 12 mission followed in November 1969. The Apollo 13 mission, launched in April 1970, experienced an explosion of the oxygen tank in its Service Module on the outbound trip to the Moon. The crew survived this accident only through the improvised use of the Lunar Module as living quarters in order to preserve the remaining capabilities of the Command Module for reentering Earth's atmosphere after they had returned from their circumlunar journey. Four more Apollo missions followed. On the final three, the crew had a small cartlike rover that allowed them to travel several kilometres from their landing site. The final mission, Apollo 17, which was conducted in December 1972, included geologist Harrison Schmitt, the only trained scientist to set foot on the Moon.

Apollo-Soyuz Test Project

An Apollo spacecraft was used for the last time in 1975. Three years earlier, as a sign of improved U.S.-Soviet relations, the two countries had agreed to carry out a joint mission in which an Apollo spacecraft carrying three astronauts would dock in orbit with a Soyuz vehicle having two cosmonauts aboard. The Apollo-Soyuz Test Project, which took place in July 1975, featured a "handshake in space" between Apollo commander Thomas Stafford and Soyuz commander Aleksey Leonov.

ORBITING SPACE PLATFORMS

Salyut 1

Space stations. By 1969, even though the U.S.S.R. was still moving forward with its lunar landing program, it had begun to shift its emphasis in human spaceflight to the development of Earth-orbiting stations in which cosmonaut crews could carry out extended observations and experiments on missions that lasted weeks or months rather than a few days. The first Soviet space station, called Salyut 1, was launched April 19, 1971. Its initial crew, Georgy Dobrovolsky, Viktor Patsayev, and Vladislav Volkov, spent 23 days aboard the station carrying out scientific studies but perished when their Soyuz spacecraft depressurized during reentry.

Skylab

With similar objectives for a long-term manned platform in space, the United States converted the third stage of a Saturn V rocket into an orbital workshop for solar and biomedical studies. This first U.S. space station, called Skylab, was launched May 14, 1973. Over a period of eight and a half months, three three-person crews using Apollo spacecraft for transport spent time aboard Skylab, with the final crew staying for 84 days.

Whereas the United States did not launch a planned second Skylab due to budgetary cuts, the Soviet Union orbit-

ed and successfully occupied five more Salyut stations in a program that continued through the mid-1980s. Two of these stations had a military reconnaissance mission, but the others were devoted to scientific studies, particularly biomedical research. The Soviet Union also launched guest cosmonauts from allied countries for short stays aboard the Salyuts 6 and 7.

These early stations were a reflection of a long-held belief among space visionaries, dating back to Tsiolkovsky at the start of the 20th century, that living and working in space, first in Earth orbit and then on the Moon, Mars, and other locations, were an important part of the human future. It also was thought that increasingly complex orbital outposts would be the first steps in a long-term process of space development and colonization. The early focus of the United States and the U.S.S.R. on sending people to the Moon for political reasons deviated from this vision, which has since returned to dominate space thinking.

Mir

The Soviet Union followed its Salyut station series with the February 1986 launch of the core element of the modular Mir space station (Figure 10). Additional modules carrying scientific equipment and expanding the living space were attached to Mir in subsequent years. In 1994–95, Valery Polyakov, a medical doctor, spent 438 continuous days aboard the station. More than 100 different people from 12 countries visited Mir, including seven American astronauts in the 1995–98 period. The station, which was initially scheduled to operate for only five years, supported human habitation until mid-2000 (continuously between 1989 and 1999), although it experienced a number of accidents and other serious problems.

International Space Station

The United States did not follow up on Skylab until 1984, when President Ronald Reagan approved a space station program and invited U.S. allies to participate. By 1988, 11 countries—Canada, Japan, and nine countries from Europe—had decided to join what was known as Space Station Freedom. Progress in developing the station was slow, however, and in 1993, newly elected President Bill Clinton ordered a sweeping redesign of the program. The United States and its existing partners invited Russia, which had inherited most of the Soviet Union's space efforts after the U.S.S.R.'s collapse in 1991, to participate in the multinational program, renamed the International Space Station (ISS). Three additional countries joined during the 1990s, making the 16-country project the largest-ever cooperative technological undertaking. The first two elements of the ISS were launched and connected in space in late 1998, and several modules and other equipment were subsequently added. Assembly and initial operation of the facility were scheduled to take place over much of the first decade of the 21st century.

The space shuttle. After the success of the Apollo 11 mission, NASA proposed an ambitious plan that included human flights to Mars, a series of large space stations to be developed during the 1970s, and a new, reusable space transportation system to send people and supplies to those stations. This plan was quickly rejected, as there was no interest in major post-Apollo space programs among the political leadership or the general public. In 1972 NASA received presidential approval to develop a partially reusable transport vehicle called a space shuttle. This vehicle was intended to carry people and as much as 29,500 kilograms (65,000 pounds) of cargo into a low Earth orbit at low cost. Based on those expectations, the United States planned to use the shuttle as its sole launch vehicle once it entered operation and to operate a shuttle fleet with a launch rate as high as 60 per year. In the absence of a space station, plans also called for having the shuttle serve double duty as a space platform to conduct in-orbit research for periods as long as two weeks. To that end, Europe pledged to contribute a pressurized laboratory, known as Spacelab, that would be carried in the shuttle's payload bay.

The space shuttle design (Figure 11) had three major components. A reusable winged orbiter would carry crew and cargo and be able to glide to a landing on a conventional runway at the end of its mission. A large external tank would carry the liquid-oxygen and liquid-hydrogen propellants for the orbiter's three powerful engines. The tank would be used only during the first eight minutes of flight; once the fuel was exhausted, it would be discarded and burn up on reentry. Two solid-fuel rockets would assist in accelerating the vehicle during the first two minutes of flight; they would then be detached and parachute into the ocean, where they would be recovered for future use. A fleet of four operational orbiters, named *Columbia, Challenger, Atlantis,* and *Discovery,* was built.

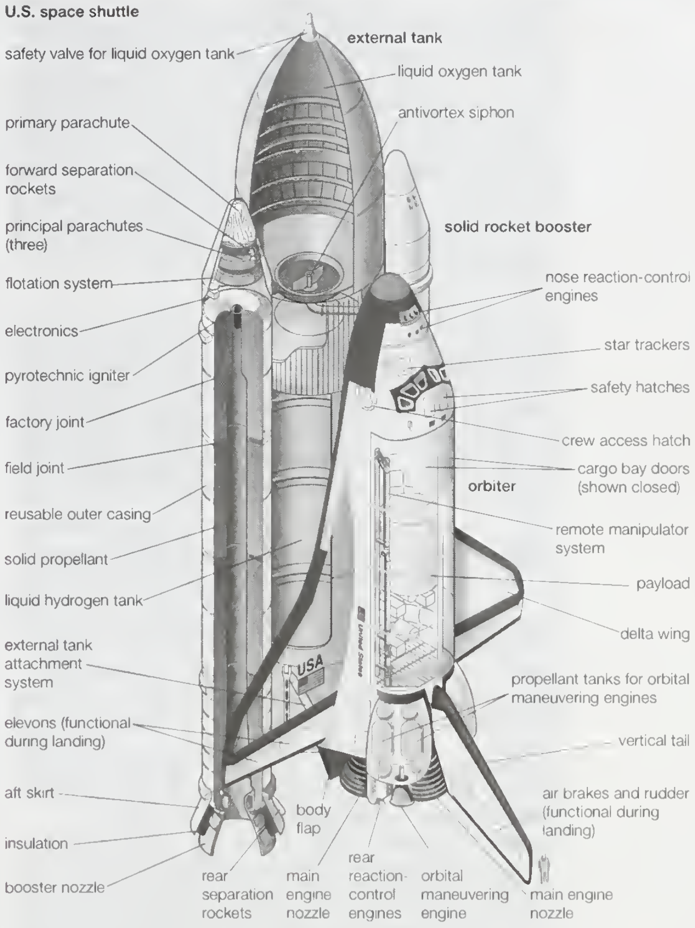

Figure 11: U.S. space shuttle, composed of a winged orbiter, an external liquid-propellant tank, and two solid-fuel rocket boosters.
Encyclopædia Britannica, Inc

After several years of technical and budgetary delays to the program, the first space shuttle flight took place on April 12, 1981; aboard were astronauts John Young, a veteran of the Gemini and Apollo programs, and Robert Crippen. With additional flights, it became evident that projections of the vehicle's operational costs and performance had been extremely optimistic. Major refurbishment was required between each launch; the highest flight rate achieved was in 1985, when the shuttle was launched nine times. Each launch cost hundreds of millions of dollars, rather than the tens of millions that had been promised in 1972. Although the space shuttle was a remarkable technological achievement as a first-generation reusable launch vehicle, the plans to use it as the only launcher for American payloads proved to be a major policy mistake.

Challenger explosion

The optimism surrounding the space shuttle program was publicly shattered on January 28, 1986, when the *Challenger* orbiter was destroyed in a catastrophic explosion 73 seconds after liftoff. Its seven-person crew perished; among them was schoolteacher Christa McAuliffe, on board as the first private citizen in space. The launch had taken place in unusually cold weather, and a sealing ring within a segment joint of one of the solid rocket boosters failed. The solid rocket broke loose and hit the external tank, rupturing it. The flame from the leaking booster ignited the shuttle's fuel, causing the explosion.

After the accident, the shuttle fleet was grounded until September 1988. A replacement orbiter, *Endeavour,* was built, but, upon the resumption of flights, the shuttle fleet was operated with much greater assurances for the safety of its crew. This limited the flight rate to six to eight missions per year. Both before and after the *Challenger* accident, the space shuttle demonstrated impressive capabilities in space operations, including the repair and redeployment of damaged satellites—most striking being the in-orbit repair of the Hubble Space Telescope in 1993. Beginning in 1998, the space shuttle was used to carry components of the ISS into orbit, along with the crews to assemble those components. It also was used to ferry people and supplies to and from the space station, the role for which it was first conceived.

SCIENCE IN SPACE

The ability to put their instruments into outer space has given scientists the opportunity to acquire new information about the natural universe—information that in many cases would be unobtainable any other way. Space science has added a new dimension to the quest for knowledge, complementing and extending what has been gained from centuries of theoretical speculations and ground-based observations.

Since Yury Gagarin's 1961 flight, space missions involving human crews have carried out a range of significant research, from on-site geological investigations on the Moon to a wide variety of observations and experiments aboard orbiting spacecraft. In particular, the presence in space of humans as experimenters and, in some cases, as experimental subjects has facilitated studies in biomedicine and materials science. Nevertheless, most space science has been carried out by robotic spacecraft in Earth orbit or on missions to various bodies in the solar system. In general, such missions are far less expensive than those involving humans and can carry sophisticated automated instruments to gather a wide variety of relevant data.

In addition to the United States and the Soviet Union, several other countries have the capability to develop and operate scientific spacecraft and thus carry out their own space science missions. They include Japan, Canada, and a number of European countries such as the United Kingdom, France, Italy, and Germany, acting alone and through cooperative organizations involving other European countries. Furthermore, many other countries have become involved in space activities through the participation of their scientists in specific missions. Bilateral or multilateral cooperation among various countries in carrying out space science missions has become the usual way of proceeding.

Categories of space science

Scientific research in space can be divided into five general areas: (1) solar and space physics, including study of the magnetic and electromagnetic fields in space and the various energetic particles also present, with particular attention to their interactions with Earth; (2) exploration of the planets, moons, asteroids, comets, meteoroids, and dust in the solar system; (3) study of the origin, evolution, and current state of the varied objects in the universe beyond the solar system; (4) research on nonliving and living materials, including humans, in the very low gravity levels of the space environment; and (5) study of Earth from space.

Solar and space physics. The first scientific discovery made with instruments orbiting in space was the existence of the Van Allen radiation belts, by Explorer 1 and other spacecraft in 1958. Subsequent space missions carried out by several countries investigated Earth's magnetosphere, the surrounding region of space in which the planet's magnetic field exerts a controlling effect. Of particular interest was—and continues to be—the interaction of the flux of charged particles emitted by the Sun, called the solar wind, with the magnetosphere. Early space science investigations showed, for example, that luminous atmospheric displays known as auroras were the result of this interaction, and scientists came to understand that the magnetosphere is an extremely complex phenomenon.

The focus of inquiry in space physics has since been extended to understanding the characteristics of the Sun, both as an average star and as the primary source of energy for the rest of the solar system, and to exploring space between the Sun and Earth and other planets. The magnetospheres of other planets, particularly Jupiter with its strong magnetic field, also have come under study. Scientists have sought a better understanding of the internal dynamics and overall behaviour of the Sun, the underlying causes of variations in solar activity, and the way in which those variations propagate through space and ultimately affect Earth's magnetosphere and upper atmosphere.

To carry out the investigations required to address these scientific questions, the United States, Europe, the Soviet Union, and Japan have developed a variety of space missions, often in a coordinated fashion. In the United States, early studies of the Sun were undertaken by a series of Orbiting Solar Observatory satellites (launched 1962–75) and the astronaut crews of Skylab in 1973–74. These were followed by the Solar Maximum Mission satellite (launched 1980). ESA developed the Ulysses mission (1990) to explore the Sun's polar regions. In the 1980s, NASA, ESA, and Japan's Institute of Space and Astronautical Science undertook a cooperative venture to develop a comprehensive series of space missions, named the International Solar-Terrestrial Physics Program, that was aimed at full investigation of the Sun-Earth connection. This program was responsible for the U.S. Wind (1994) and Polar (1996) spacecraft, the European SOHO (1995) and Cluster (2000) missions, and the Japanese Geotail satellite (1992).

International Solar-Terrestrial Physics Program

Solar system exploration. From the start of space activity, scientists recognized that spacecraft could gather scientifically valuable data about the various planets, moons, and smaller bodies in the solar system. Both the United States and the U.S.S.R. attempted to send robotic missions to the Moon in the late 1950s. The first four U.S. Pioneer spacecraft, Pioneer 0–3, launched in 1958, were not successful in returning data about the Moon. The fifth mission, Pioneer 4 (1959), was the first U.S. spacecraft to escape Earth's gravitational pull; it flew by the Moon at twice the planned distance but returned some useful data. Three Soviet missions, Luna 1–3, explored the vicinity of the Moon in 1959, confirming that it had no appreciable magnetic field and sending back the first-ever images of its far side. Luna 1 was the first spacecraft to fly past the Moon, beating Pioneer 4 by two months; Luna 2, in making a hard landing on the lunar suface, was the first spacecraft to strike another celestial object. Later Luna spacecraft soft-landed on the Moon, and some gathered soil samples and returned them to Earth.

In the 1960s the United States became the first country to send a spacecraft to the vicinity of other planets—Mariner 2 flew by Venus in December 1962, and Mariner 4 flew past Mars in July 1965. Among significant accomplishments of planetary missions in succeeding decades were the U.S. Viking landings on Mars in 1976 and the Soviet Venera explorations of the atmosphere and surface of Venus from the mid-1960s to the late 1970s. In the years since, the United States has continued an active program of solar system exploration, as did the Soviet Union until its dissolution in 1991. Japan has launched missions to the Moon, Mars, and Halley's Comet. Europe's only independent solar system mission, Giotto, also flew by Halley; in addition, Europe has participated in several U.S. solar system missions.

Three stages of solar system exploration

Early on, scientists planned to conduct solar system exploration in three stages: initial reconnaissance from spacecraft flying by a planet, comet, or asteroid; detailed surveillance from a spacecraft orbiting the object; and on-site research after landing on the object or, in the case of the giant gas planets, by sending a probe into its atmosphere. By the start of the 21st century, all three of those stages had been carried out for the Moon, Venus, Mars, Jupiter, and a near-Earth asteroid. Several Soviet and U.S. robotic spacecraft have landed on Venus and the Moon, and the United States has landed spacecraft on the surface of Mars. A long-term, detailed surveillance of Jupiter and its moons began in 1995 when the U.S. Galileo spacecraft took up orbit around the planet, at the same time releasing a probe into the turbulent Jovian atmosphere. In 2001, the U.S. Near Earth Asteroid Rendezvous (NEAR) spacecraft landed on the asteroid Eros and transmitted information from its surface for more than two weeks. Among the rocky inner planets, only Mercury has been visited just

Galileo and NEAR

once—the U.S. Mariner 10 probe made three flybys of the planet in 1974–75.

As of 2001 the exploration of the other giant gas planets—Saturn, Uranus, and Neptune—remained at the flyby stage. In a series of U.S. missions launched in the 1970s, Pioneer 10 flew by Jupiter, whereas Pioneer 11 and Voyager 1 and 2 flew by both Jupiter and Saturn. Voyager 2 then went on to travel past Uranus and Neptune. The U.S. Cassini spacecraft, launched in 1997, was scheduled to begin long-term surveillance mission in the Saturnian system in 2004, during which its European-built Huygens probe was to descend to the surface of Titan, Saturn's largest moon. Thus, every major body in the solar system except Pluto and its moon, Charon, has been visited at least once by a spacecraft.

What has been learned to date confirms that Earth and the rest of the solar system formed at about the same time from the same cloud of gas and dust surrounding the Sun. The four outer giant gas planets are roughly similar in size and chemical composition, but each has a set of moons that differ widely in their characteristics. The four rocky inner planets had a common origin but have followed very different evolutionary paths and today have very different surfaces, atmospheres, and internal activity. Ongoing comparative study of the evolution of Venus, Mars, and Earth could provide important insights into Earth's future and its continued ability to support life.

Search for extraterrestrial life

The question of whether life has ever existed elsewhere in the solar system continues to intrigue both scientists and the general public. The United States sent two Viking spacecraft to land on the surface of Mars in 1976. Each contained three experiments intended to search for traces of organic material that might indicate the presence of past or present life forms; none of the experiments produced positive results. Twenty years later, a team of scientists studying a meteorite of Martian origin found in Antarctica announced the discovery of possible microscopic fossils resulting from past organic life. Their claim was not universally accepted, but it led to an accelerated program of Martian exploration. A major goal of this program is to return samples of the Martian surface to Earth for laboratory analysis.

The Galileo mission has provided images and other data related to Jupiter's moon Europa that suggest the presence of a liquid water ocean beneath its icy crust. Future missions will seek to confirm the existence of this ocean and search for evidence of organic or biological processes in it.

Exploring the universe. Until the dawn of spaceflight, astronomers were limited in their ability to observe objects beyond the solar system to those portions of the electromagnetic spectrum that could penetrate Earth's atmosphere. These portions included the visible region, parts of the ultraviolet region, and most of the radio-frequency region. The ability to place instruments on a satellite operating above the atmosphere opened the possibility of observing the universe in all regions of the spectrum. Even operating in the visible region, a space-based observatory could avoid the problems caused by atmospheric turbulence and airglow.

Since the 1960s, satellites have been launched by a number of countries to explore cosmic phenomena in the gamma-ray, X-ray, ultraviolet, visible, and infrared regions. More recently, space-based radio astronomy has been pursued. In the last decades of the 20th century, the United States embarked on the development of a series of long-duration orbital facilities collectively called the Great Observatories. They include the Hubble Space Telescope, launched in 1990 for observations in the visible and ultraviolet regions; the Compton Gamma Ray Observatory, launched in 1991; the Chandra X-Ray Observatory, launched in 1999; and the Space Infrared Telescope Facility, to be launched in 2002. Europe and Japan have also been active in space-based astronomy and astrophysics. The results of these space investigations have made major contributions to an understanding of the origin, evolution, and likely future of the universe, galaxies, stars, and planetary systems.

Great Observatories program

Microgravity research. A spacecraft orbiting Earth is essentially in a continual state of free fall. All objects associated with the spacecraft, including any crew and other contents, are accelerating—*i.e.,* falling freely—at the same rate in Earth's gravitational field. As a result, these objects do not "feel" the presence of the Earth's gravity but instead experience a state of weightlessness, or zero gravity. True zero gravity, however, is experienced only at the centre of mass of a freely falling object. With increasing distance from the centre of mass, the influence of gravity increases in directions perpendicular to the object's flight path. These constant but tiny accelerations make necessary the use of the term *microgravity* to describe the space environment. (It is possible to create a similar absence of gravity's effects only briefly on Earth or in an aircraft.) Human activity or operating equipment in a spacecraft causes vibrations that impart additional accelerations and so raise gravity levels, which can make it difficult to carry out highly sensitive experiments under sufficiently low microgravity conditions. Although spacecraft designers cannot totally eliminate gravitational effects, they hope to reduce them in some parts of the International Space Station to one microgravity—one-millionth of Earth's gravity—by isolating those areas from vibrations and other disturbances as much as possible.

The opportunity to carry out experiments in the absence of gravity has interested scientists from the beginning of activities in orbit. In addition to concern about the effects of the weightlessness on humans sent into space, scientists are interested in its effects on the reproductive and developmental cycles of plants and animals other than humans. The overall goal is to use space-based research to add to the general understanding of a wide range of biological processes.

Life-sciences experiments were carried out on the Skylab, Salyut, and Mir space stations and will constitute a significant portion of work aboard the ISS. Such research also has been conducted on space shuttle missions, particularly within the Spacelab facility. In addition, the Soviet Union and United States launched a number of robotic satellites dedicated to life-sciences research. Together these experiments have involved a wide range of nonhuman organisms, from bacteria, plants, and invertebrate animals to fish, birds, frogs, turtles, and mammals such as rats and monkeys. Human crew members also have served as experimental subjects for research on such topics as the functioning of the neurological system and the process of aging. In October 1998, U.S. senator and former Mercury astronaut John Glenn at age 77 returned to space on a shuttle mission dedicated to life-sciences research, which included studies of similarities between the aging process and the body's response to weightlessness.

John Glenn's return to space

The microgravity environment also offers unique conditions for experiments designed to explore the behaviour of materials. Among the areas of inquiry are biotechnology, combustion science, fluid physics, fundamental physics, and materials science. Experiments in the microgravity environment on various materials including metals, alloys, electronic and photonic materials, composites, colloids, glasses and ceramics, and polymers have resulted in a greater understanding of the role of gravity in similar laboratory and manufacturing processes on Earth. Although microgravity research is still largely at the basic level, scientists and engineers hope that additional work—another major focus for the ISS—will lead to practical knowledge of great usefulness to manufacturing processes on Earth.

Observing Earth. Satellites, space stations, and space shuttle missions have provided a new perspective for scientists to collect data about Earth itself. In addition to practical applications (see below), Earth observation from space has made significant contributions to fundamental knowledge. An early and continuing example is the use of satellites to make various geodetic measurements, which has allowed precise determinations of Earth's shape, internal structure, and rotational motion and the tidal and other periodic motions of the oceans. Fields as diverse as archaeology, seismology, and oceanography likewise have benefited from observations and measurements made from orbit.

Scientists have begun to use observations from space as part of comprehensive efforts in fields such as oceanography and ecology to understand and model the causes, processes, and effects of global climate change, including the influence of human activities. The goal is to obtain comprehensive sets of data over meaningful time spans about key physical, chemical, and biological processes that are shaping the planet's future.

SPACE APPLICATIONS

Space visionaries in the early 20th century recognized that putting satellites into orbit could furnish direct and tangible benefits to people on Earth. For example, the English writer Arthur C. Clarke in 1945 described a way in which three satellites above the Equator in a geostationary orbit could relay communications around the globe.

Public-good and commercial applications

Space development, the practical application of the capabilities of spacecraft and of the data collected from space, has evolved in parallel with space exploration. There are two general categories of space applications. One provides benefits that are considered public goods—*i.e.,* that cannot easily be marketed to individual purchasers—and thus are usually provided by governments using public funds. Examples of public-good space applications include meteorology; navigation, position location, and timing; and military and national security uses. The other category of applications provides goods or services that can be sold to purchasers at a profit. These applications are the basis for the commercial development of space by the private sector. Examples of existing commercial space applications include various forms of telecommunications via satellites, remote sensing of Earth's surface, and commercial space transportation. Satellite communications was the first commercial space application, and it has remained the most successful one.

Meteorology. Meteorologists initially thought that satellites would be used primarily to observe cloud patterns and thus provide warnings of impending storms. They did not expect space observations to be central to improved weather forecasting overall. Nevertheless, as the technology of space-based instrumentation became more sophisticated, satellites were called upon to provide three-dimensional profiles of additional variables in the atmosphere including temperature, moisture content, and wind speed. These data have become critical to modern weather forecasting.

Multinational involvement

Meteorological satellites are placed in one of two different kinds of orbit. Satellites in geostationary orbit provide continuous images of cloud patterns over large areas of Earth's surface. From changes in those patterns, meteorologists can deduce wind speeds and locate developing storms. Satellites in lower orbits aligned in a north-south direction, called polar orbits, can obtain more detailed data about changing atmospheric conditions. They also provide repetitive global coverage as Earth rotates beneath their orbit. In the United States, military and civilian agencies each have developed independent polar-orbiting meteorological satellite systems; China, Europe, and the Soviet Union also have deployed their own polar-orbiting satellites. The United States, Europe, the Soviet Union, India, and Japan have orbited geostationary meteorological satellites.

Although the research and development needed to produce meteorological satellites has been carried out by various space agencies, control over satellite operation usually has been handed over to organizations with general responsibility for weather forecasting. In the United States, the National Oceanographic and Atmospheric Administration (NOAA) operates geostationary and polar-orbiting satellites for short- and long-term forecasting, and plans were under way in 2001 to merge that country's civilian and military polar satellite programs under NOAA management. In Europe, an intergovernmental organization called Eumetsat was created in 1986 to operate Europe's meteorological satellites and provide their observations to national weather services.

Positioning, navigation, and timing. In 1957, scientists tracking the first satellite, Sputnik 1, found that they could plot the satellite's orbit very precisely by analyzing the Doppler shift in the frequency of its transmitted signal with respect to a fixed location on Earth. They realized that if this process could be reversed—*i.e.,* if the orbits of several satellites were precisely known—it would be possible to identify one's location on Earth using information from those satellites.

Navstar GPS and GLONASS

This realization, coupled with the need to establish the position at sea of submarines carrying ballistic missiles, led the United States and the Soviet Union each to develop satellite-based navigation systems in the 1960s and early '70s. Those systems, however, did not provide highly accurate information and were unwieldy to use. The two countries then developed second-generation products—the U.S. Navstar Global Positioning System (GPS) and the Soviet Global Navigation Satellite System (GLONASS)—that did much to solve the problems of their predecessors. The original purpose of the systems was the support of military activities, and, at the start of the 21st century, they continued to operate under military control.

The GPS system requires a minimum of 24 satellites, with four satellites distributed in each of six orbits. Deployment of the full complement of satellites was completed in 1994 and included provision for continual replenishment and updating and the maintenance of several spare satellites in orbit. Each satellite carries four atomic clocks accurate to one nanosecond. Because the satellites' orbits are maintained very precisely by ground controllers and the time signals from each satellite are highly accurate, users with a GPS receiver can determine their distance from each of a minimum of four satellites and, from this information, pinpoint their exact location with an accuracy of approximately 18 metres (59 feet) horizontally and 28 metres (92 feet) vertically. The GLONASS system, which became operational in 1996, functions on the same general principles as GPS. A fully deployed system would consist of 24 satellites distributed in three orbits. Because of Russia's economic difficulties, however, GLONASS has not been well maintained and replacement satellite deployment has been slow.

Notwithstanding the military origin of the GPS and GLONASS systems, civilian users have proliferated. They range from wilderness campers, farmers, golfers, and recreational sailors to surveyors, car rental firms, and the world's airlines. The timing information from GPS satellites is also used by the Internet and other computer networks to manage the flow of information. The United States regards GPS as a global utility to be offered free of charge to all users, and it has stated its intent to maintain and upgrade the system into the indefinite future. Concern has been expressed, however, that important worldwide civilian activities such as air-traffic control should not depend on a system controlled by one country's military forces. In response, Europe began in the late 1990s to develop its own navigation satellite system, called Galileo, to be operated under civilian control.

Military and national security uses of space. Those countries and organizations with armed forces deployed abroad were quick to recognize the great usefulness of space-based systems in military operations. The United States, the Soviet Union, the United Kingdom, the North Atlantic Treaty Organization (NATO), and, to a lesser degree, other European countries and China have deployed increasingly sophisticated space systems—including satellites for communications, meteorology, and positioning and navigation—that are dedicated to military uses. In addition, the United States and the Soviet Union have developed satellites to provide early warning of hostile missile launches.

To date, military space systems have served primarily to enhance the effectiveness of ground-, air-, and sea-based military forces. Commanders rely on satellites to communicate with troops on the front lines, and in extreme circumstances national authorities could use them to issue the commands to launch nuclear weapons. Meteorological satellites assist in planning air strikes, and positioning satellites are used to guide weapons to their targets with high accuracy.

Despite the substantial military use of space, no country has deployed a space system capable of attacking a satellite in orbit or of delivering a weapon to a target on Earth. Nevertheless, as more countries acquire military space capabilities and as regional and local conflicts persist around the world, it is not clear whether space will continue to be treated as a weapons-free sanctuary.

Intelligence-gathering satellites

In addition to recognizing the value of space systems in warfare, national leaders in the United States and the Soviet Union realized early on that the ability to gather information about surface-based activities such as weapons development and deployment and troop movements would assist them in planning their own national security activities. As a result, both countries have deployed a variety of space systems for collecting intelligence. They include reconnaissance satellites that provide high-resolution images of Earth's surface in close to real time for use in identifying threatening activities, planning military operations, and monitoring arms-control agreements. Other satellites collect electronic signals such as telephone, radio, and Internet messages and other emissions, which can be used to determine the type of activities that are taking place in a particular location. Most national-security space activity is carried out in a highly secret manner. As the value to national security of such satellite systems has become evident, other countries, such as France, China, India, and Israel, have developed similar capabilities, and still others have begun planning their own systems.

Telstar

Satellite telecommunications. Although some early space experiments explored the use of large orbiting satellites as passive reflectors of signals from point to point on Earth, most work in the late 1950s and early '60s focused on the technology by which a signal sent from the ground would be received by satellite, electronically processed, and relayed to another ground station. American Telephone and Telegraph, recognizing the commercial potential of satellite communications, in 1962 paid NASA to launch its first Telstar satellite. Because that satellite, which operated in a fairly low orbit, was in range of any one receiving antenna for only a few minutes, a large network of such satellites would have been necessary for an operational system. Engineers from the American firm Hughes Aircraft, led by Harold Rosen, developed a design for a satellite that would operate in geostationary orbit. Aided by research support from NASA, the first successful geostationary satellite, Syncom 2, was launched in 1963.

Comsat and Intelsat

The United States also took the lead in creating the organizational framework for communications satellites. Establishment of the Communications Satellite Corporation (Comsat) was authorized in 1962 to operate American communications satellites, and two years later an international agency, the International Telecommunications Satellite Organization (Intelsat), was formed at the proposal of the United States to develop a global network. Comsat, the original manager of Intelsat, decided to base the Intelsat network on geostationary satellites. The first commercial communications satellite, Intelsat 1, also known as Early Bird, was launched in 1965. Intelsat completed its initial global network with the stationing of a satellite over the Indian Ocean in mid-1969, in time to televise the first Moon landing around the world.

The original use of communications satellites was to relay voice, video, and data from one relatively large antenna to a second, distant one, from which the communication then would be distributed over terrestrial networks. This point-to-point application introduced international communications to many new areas of the world, and in the 1970s it also was employed domestically within a number of countries, especially the United States. As undersea fibre-optic cables improved in carrying capacity and signal quality, they became competitive with communications satellites; the latter responded with comparable technological advances that allowed these space-based systems to meet the challenge. A number of companies in the United States and Europe manufacture communications satellites and vie for customers on a global basis.

Direct TV broadcasting

Other space-based communications applications have appeared, the most prominent being the broadcast of signals, primarily television programming, directly to small antennas serving individual households. A similar emerging use is the broadcast of audio programming to small antennas in locations ranging from rural villages in the developing world to individual automobiles. International private satellite networks have emerged as rivals to the government-owned Intelsat, which as of 2001 was itself being transformed into a private-sector organization.

Yet another service that has been devised for satellites is communication with and between mobile users. In 1979 the International Maritime Satellite Organization (Inmarsat) was formed to relay messages to ships at sea. With the growth of personal mobile communications such as cellular telephone services, several attempts were made beginning in the late 1990s to establish satellite-based systems for this purpose. Typically employing constellations of many satellites in low Earth orbit, they experienced difficulty competing with ground-based cellular systems.

Remote sensing. Remote sensing is a term applied to the use of satellites to observe various characteristics of Earth's land and water surfaces in order to obtain information valuable in mapping, mineral exploration, land-use planning, resource management, and other activities. Remote sensing is carried out from orbit with multispectral sensors—*i.e.,* observations are made in several discrete regions of the electromagnetic spectrum that include visible light and usually other wavelengths. From multispectral imagery, analysts are able to derive information on such varied areas of interest as crop condition and type, pollution patterns, and sea conditions.

Landsat and SPOT

Because many applications of remote sensing have a public-good character, a commercial remote-sensing industry has been slow to develop. In addition, the secrecy surrounding intelligence-gathering satellites set stringent limits during the Cold War era on the capabilities that could be offered on a commercial basis. The United States launched the first remote-sensing satellite, NASA's Landsat 1 (originally called Earth Resources Technology Satellite), in 1972. The goals of the Landsat program, which by 1999 had included six successful satellites, were to demonstrate the value of multispectral observation and to prepare the system for transfer to private operators. Despite two decades of attempts at such a transfer, Landsat remained a U.S. government program at the start of the 21st century. In 1986, France launched the first of its SPOT remote-sensing satellites and created a marketing organization, SpotImage, to promote use of its imagery. Both Landsat's and SPOT's multispectral images offered a moderate ground resolution of 10–30 metres (about 30–100 feet). Japan and India also have launched multispectral remote-sensing satellites.

High-resolution remote sensing

In the 1990s, with the end of the Cold War, some of the technology used in reconnaissance satellites was declassified. This allowed several American firms to begin developing high-ground-resolution (less than one metre [3.3 feet]) commercial remote-sensing satellites. The first commercial high-resolution satellite, called Ikonos 1, was launched by the Space Imaging Company in 1999. Among major customers for high-resolution imagery are governments that lack their own reconnaissance satellites. The global availability of imagery previously available only to the leaders of a few countries is troubling to some observers, who express concern that it could lead to increased military activity. Others suggest that this widespread availability will contribute to a more stable world.

Commercial space transportation. The prosperity of the communications satellite business has been accompanied by a willingness of the private sector to pay substantial sums for the launch of its satellites. Initially, most commercial communications satellites went into space on U.S.-government-operated vehicles. When the space shuttle was declared operational in 1982, it became the sole American launch vehicle providing such services. After the 1986 *Challenger* accident, however, the shuttle was prohibited from launching commercial payloads. This created an opportunity for the private sector to employ existing expendable launch vehicles such as the Delta, Atlas, and Titan as commercial launchers. In the years since, a vigorous American commercial space transportation industry has emerged. Whereas the Titan was not a commercial success, the other two vehicles found numerous commercial customers.

Europe followed a different path to commercial space transport. After deciding in the early 1970s to develop the Ariane launcher, it created under French leadership a marketing organization called Arianespace to seek commercial launch contracts for the vehicle. In the mid-1980s, both the

U.S.S.R. and China initiated efforts to attract commercial customers for their launch vehicles. As the industry developed in the 1990s, the United States initiated joint ventures with Russia and Ukraine to market their launchers; Europe also created a similar alliance with Russia.

In 2000 there were 35 commercial launches. In the future, as other countries enter the competition for commercial launch contracts and as new types of launch vehicles are developed, the space business may experience an oversupply of commercial launch capacity. (J.M.Lo.)

BIBLIOGRAPHY

Surface and subsurface exploration. Texts on methodology and discoveries include ARTHUR W. ROSE, HERBERT E. HAWKES, and JOHN S. WEBB, *Geochemistry in Mineral Exploration,* 2nd ed. (1979); ROBERT F. LEGGET and ALLEN W. HATHEWAY, *Geology and Engineering,* 3rd ed. (1988); *Sampling of Soil and Rock* (1971), published by the American Society for Testing and Materials; MARTIN H.P. BOTT, *Interior of the Earth: Its Structure, Constitution, and Evolution,* 2nd ed. (1982); GEORGE D. GARLAND, *Introduction to Geophysics: Mantle, Core, and Crust,* 2nd ed. (1979); ROBERT E. SHERIFF (compiler), *Encyclopedic Dictionary of Exploration Geophysics,* 3rd ed. (1991); ROBERT E. SHERIFF, *Geophysical Methods* (1989); ROBERT E. SHERIFF and L.P. GELDART, *Exploration Seismology,* 2 vol. (1982–83); W.M. TELFORD, L.P. GELDART, and ROBERT E. SHERIFF, *Applied Geophysics,* 2nd ed. (1980); CHUJI TSUBOI, *Gravity* (1983; originally published in Japanese, 1979); W.D. PARKINSON, *Introduction to Geomagnetism* (1983); J.A. JACOBS, *A Textbook on Geonomy* (1974); and FLOYD F. SABINS, JR., *Remote Sensing: Principles and Interpretation,* 2nd ed. (1987). (R.E.Sh.)

Undersea exploration. The classical tools of the oceanographer are described by H.U. SVERDRUP, MARTIN W. JOHNSON, and RICHARD H. FLEMING, *The Oceans* (1942, reissued 1970). More recent texts on oceanography and marine biology include M. GRANT GROSS, *Oceanography, a View of the Earth,* 5th ed. (1990); GEORGE L. PICKARD and WILLIAM J. EMERY, *Descriptive Physical Oceanography,* 5th enlarged ed. (1990); JAMES P. KENNETT, *Marine Geology* (1982); BRUCE A. WARREN and CARL WUNSCH (eds.), *Evolution of Physical Oceanography* (1981); JAMES L. SUMICH, *An Introduction to the Biology of Marine Life,* 5th ed. (1992); M.N. HILL *et al.* (eds.), *The Sea* (1962–); and J.P. RILEY and G. SKIRROW (eds.), *Chemical Oceanography,* 2nd ed., 8 vol. (1975–83).

Exploration and discovery are chronicled in RACHEL L. CARSON, *The Sea Around Us,* special ed. (1989); JAMES DUGAN and RICHARD VAHAN (eds.), *Men Under Water* (1965); and HARRIS B. STEWART, JR., *Deep Challenge* (1966). Also informative is the documentary of famous explorers, such as the books by WILLIAM BEEBE, *Half Mile Down* (1934, reissued 1951); JACQUES PICCARD and ROBERT S. DIETZ, *Seven Miles Down* (1961); GEORGE STEPHEN RITCHIE, *Challenger: The Life of a Survey Ship* (1957); HELEN RAITT, *Exploring the Deep Pacific,* 2nd ed. (1964); WILLARD BASCOM, *A Hole in the Bottom of the Sea: The Story of the Mohole Project* (1961); FRANCIS P. SHEPARD, *The Earth Beneath the Sea,* rev. ed. (1967); and DANIEL BEHRMAN, *The New World of the Oceans* (1969). Information on exploration and survey vessels in operation today may be found in an annually updated loose-leaf catalog, *Oceanography Vessels of the World* (1961–), published by the U.S. Naval Oceanographic Office. STEWART B. NELSON, *Oceanographic Ships, Fore and Aft* (1971, reprinted 1983), provides a complete history of U.S. vessels up to the time of publication. See also JACQUES COUSTEAU and ALEXIS SIVERINE, *Jacques Cousteau's Calypso* (1983; originally published in French, 1978); R. FRANK BUSBY, *Manned Submersibles* (1976), on their design and operation; and KENNETH J. HSÜ, *Challenger at Sea,* trans. from German (1992).

Modern undersea explorers are strongly dependent on innovative engineering and technology, such as that treated in *Jane's Ocean Technology, 1979–80* (1979); JOHN J. MYERS (ed.), *Handbook of Ocean and Underwater Engineering* (1969); JOHN F. BRAHTZ (ed.), *Ocean Engineering* (1968); and ROBERT L. WIEGEL, *Oceanographical Engineering* (1964). See also JOHN BRACKETT HERSEY (ed.), *Deep-Sea Photography* (1967); J.F.R. GOWER (ed.), *Oceanography from Space* (1981); G.A. MAUL, *Introduction to Satellite Oceanography* (1985); and F. DOBSON, L. HASSE, and R. DAVIS (eds.), *Air-Sea Interaction: Instruments and Methods* (1980). (A.B.R./D.J.Ba./Ed.)

Space exploration. Broad coverage of space activities can be found in MICHAEL RYCROFT (ed.), *The Cambridge Encyclopedia of Space* (1990; originally published in French, 1987). An overall history of space exploration is WILLIAM E. BURROWS, *This New Ocean: The Story of the First Space Age* (1998). WALTER A. MCDOUGALL, *The Heavens and the Earth: A Political History of the Space Age* (1985, reissued 1997), traces the U.S.-Soviet rivalry that led to the space race and comments on its impact on the two countries' societies. Earlier historical discussions include WILLY LEY, *Rockets, Missiles, and Men in Space,* newly rev. and expanded ed. (1968); and WERNHER VON BRAUN, FREDERICK I. ORDWAY III, and DAVID DOOLING, *Space Travel: A History,* 4th ed. (1985). FRANK H. WINTER, *Rockets into Space* (1990), provides an account of the development of rocketry. Speculative discussions of the promises of space exploration include ARTHUR C. CLARKE (compiler and ed.), *The Coming of the Space Age: Famous Accounts of Man's Probing of the Universe* (1967, reissued 1970); HARRY L. SHIPMAN, *Humans in Space: 21st Century Frontiers* (1989); CARL SAGAN, *Pale Blue Dot: A Vision of the Human Future in Space* (1994, reissued 1997); and ROBERT ZUBRIN and RICHARD WAGNER, *The Case for Mars: The Plan to Settle the Red Planet and Why We Must* (1996).

Many early American astronauts have written of their experiences. The best of these works is MICHAEL COLLINS, *Carrying the Fire: An Astronaut's Journeys* (1974, reissued 2001). An account of the Apollo program that is focused on astronauts is ANDREW CHAIKIN, *A Man on the Moon: The Voyages of the Apollo Astronauts* (1994, reissued in 3 vol., 1999); this book served as the basis for a video series, *From the Earth to the Moon* (1998), produced by TOM HANKS. A failed Apollo mission is the subject of the theatrical film *Apollo 13* (1995). The best account of Apollo from the perspective of its managers and engineers is CHARLES MURRAY and CATHERINE BLY COX, *Apollo: The Race to the Moon* (1989). A noted author offers his impressions of Apollo in NORMAN MAILER, *Of a Fire on the Moon* (1970, reissued 1985; also published as *A Fire on the Moon,* 1970). TOM WOLFE, *The Right Stuff,* new ed. (1983, reissued 1997), provides an account of the early days of U.S. human spaceflight. JOHN M. LOGSDON, *The Decision to Go to the Moon: Project Apollo and the National Interest* (1970, reissued 1976), traces the political underpinnings of the Apollo program. An extensive account of the Soviet space program during the race to the Moon is ASIF A. SIDDIQI, *Challenge to Apollo: The Soviet Union and the Space Race, 1945–1974* (2000).

The origins of U.S. post-Apollo spaceflight programs are discussed in T.A. HEPPENHEIMER, *The Space Shuttle Decision: NASA's Search for a Reusable Space Vehicle* (1999); and HOWARD E. MCCURDY, *The Space Station Decision: Incremental Politics and Technological Choice* (1990). Events leading to the 1986 *Challenger* accident are detailed in JOSEPH J. TRENTO, *Prescription for Disaster* (1987). A selective view of U.S.-Russian cooperation in human spaceflight is found in BRYAN BURROUGH, *Dragonfly: NASA and the Crisis Aboard Mir* (1998, reissued 2000).

Available in addition to the works cited above are published studies, sponsored by the NASA History Program, of almost every one of the agency's space programs. Original documents tracing the history of the U.S. space program are reprinted in JOHN M. LOGSDON *et al.* (eds.), *Exploring the Unknown: Selected Documents in the History of the U.S. Civil Space Program* (1995–).

A comprehensive discussion of European space activities up to 1987 is provided in J. KRIGE, A. RUSSO, and L. SEBESTA, *A History of the European Space Agency 1958–1987,* 2 vol. (2000). ROGER M. BONNET and VITTORIO MANNO, *International Cooperation in Space: The Example of the European Space Agency* (1994), elaborates on international space activities from a European perspective. Other national space efforts are described in BRIAN HARVEY, *The Chinese Space Programme: From Conception to Future Capabilities* (1998), *The Japanese and Indian Space Programmes: Two Roads into Space* (2000), and *Russia in Space: The Failed Frontier?* (2001).

Discussions of various space science efforts include HOMER E. NEWELL, *Beyond the Atmosphere: Early Years of Space Science* (1980); BRUCE MURRAY, *Journey into Space: The First Three Decades of Space Exploration* (1989); and WILLIAM E. BURROWS, *Exploring Space: Voyages in the Solar System and Beyond* (1990); the last two works deal with U.S. missions to explore the solar system. Also pertinent is ROBERT W. SMITH, *The Space Telescope: A Study of NASA, Science, Technology, and Politics* (1989, reissued 1993).

The origins of reconnaissance satellite programs are covered in DWAYNE A. DAY, JOHN M. LOGSDON, and BRIAN LATELL (eds.), *Eye in the Sky: The Story of the Corona Spy Satellites* (1998). Subsequent spy satellite programs are discussed in JEFFREY T. RICHELSON, *America's Secret Eyes in Space: The U.S. Keyhole Spy Satellite Program* (1990); and WILLIAM E. BURROWS, *Deep Black: Space Espionage and National Security* (1986, reissued 1988). Early debates over the military use of space are described in PAUL B. STARES, *The Militarization of Space: U.S. Policy, 1945–1984* (1985); and more recent debates on this issue are summarized in PETER L. HAYS *et al., Spacepower for a New Millennium: Space and U.S. National Security* (2000).

HEATHER E. HUDSON, *Communication Satellites: Their Development and Impact* (1990), gives a synopsis of progress in communications satellites. Controversies surrounding the development of Earth observation satellites are followed in PAMELA E. MACK, *Viewing the Earth: The Social Construction of the Landsat Satellite System* (1990). (J.M.Lo.)

Family and Kinship

Family and kinship are among the most important aspects of human society. They play a central part in the social organization of peoples throughout the world. Nevertheless, both the organization of the family unit and the structure of kinship relations vary from society to society and through time.

The study of family and kinship falls particularly within the scope of three academic disciplines: sociology, anthropology, and social history. Sociological studies tend to concentrate on the form and organization of the modern family and on the social problems that surround family life. Anthropological studies also frequently concern the family, but their emphasis is on the variety of family organizations and on cross-cultural comparisons. Anthropologists are also interested in kinship ties and obligations beyond the immediate family, since these are often extremely important in small-scale nonindustrialized societies, on which anthropological studies tend to concentrate. Social and economic historians, particularly those who practice in the subdiscipline known as family history, utilize the perspectives of a variety of disciplines, including psychology and economics, as well as sociology and anthropology.

This article discusses the history and structure of the family, with emphasis on the Western family, although comparisons are made with family and kinship structures of other cultures. Theoretical approaches to the study of family and kinship are also discussed, as are the types of kinship terminologies, descent systems, and marriage systems found in cultures throughout the world. For discussions of the family in legal systems, particularly those of the West, see the articles FAMILY LAW and INHERITANCE AND SUCCESSION. Many of the stages of life discussed here in their familial contexts are also treated in BEHAVIOUR, THE DEVELOPMENT OF HUMAN. For a discussion of reproductive and emotional aspects of the family, see SEX AND SEXUALITY. For a discussion of family planning, see BIRTH CONTROL.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 513 and 522, and the *Index*.

The article is divided into the following sections:

Family history

Western society since medieval times has been characterized by a great diversity of family organization. This diversity has had several often interrelated aspects, including geographic region, occupation, social class, and whether the family in question was rural or urban. Historically, there were considerable differences between different regions of Europe and even between different areas in the same country. Aristocrats and commoners established family customs and social institutions peculiar to their respective social classes, as did merchants and peasants. In addition, ethnic and religious minorities frequently established their own unique patterns of family life in accord with traditions and moral values that were often at variance with the rest of society.

APPROACHES TO FAMILY HISTORY

The task of interpreting and explaining the diversity of family organization in historical times has fallen to the field of family history. Family history emerged in the 1960s as a major focus of interest within the broader field of economic and social history. Because family history draws on the methods and theories of several social sciences, it has developed its own diversity of approaches to the understanding of its subject. Three major areas of interest are relevant here; the British family historian Michael Anderson labeled them the sentiments approach, the demographic approach, and the household economics approach.

The sentiments approach. The sentiments approach emerged from the interest of many scholars in the emotional ties between family members. Proponents of this approach try to understand the character of the family as it has changed through time. Topics of interest include the nature of conjugal and parent–child relationships, courtship practices, attitudes toward sex, and the relative importance of privacy and individualism in the family context.

Most proponents of the sentiments approach argue that changes in family behaviour are the result of changes in other aspects of culture. The wider society, as it undergoes change, creates cultural values affecting the family. Religious and philosophical ideas, for example, may play a part in shaping attitudes toward individualism or social equality. Even laissez-faire capitalism, according to some writers, played a part in the development of trends toward sexual freedom. General social trends and social revolutions, such as the Reformation and the Industrial Revolution, ultimately affect the behaviour and outlook of ordinary people in their family relations. The great difficulty in pursuing this approach, however, is that documentary sources are not always helpful in providing the kind of information these arguments require. Relating broad social changes to changes in sentiment is often done only through educated speculation.

Studying parish registers

The demographic approach. This approach favours more limited objectives, and its methods are akin to those of the natural sciences. Rather than literary sources, which are more frequently used by those who follow the sentiments or household economics approach, demographers concentrate on available data on households, baptisms, marriages, and burials. Parish registers in many European countries provide a large amount of source material of this kind, often going back to the 16th century. Historical demographers can use these data to build up a picture of family life at any given place and time—a particular village, for example, or a specific occupational group or social class.

The main problem of this approach is that the available data may be too incomplete or inaccurate for making useful generalizations. The original documentation may have been made for purposes of taxation or military recruitment; certainly it was not made with the interests of historians in mind. As a result, the technique of the historical demographer depends on "family reconstitution." If a range of sources is present, the reconstruction of household size and composition, marriage patterns, and a number of other features of family organization is possible, but it is still problematic.

The family as an economic unit

The household economics approach. This approach is the broadest of the three. Its proponents try to take into greater account the methods and theories of other social sciences, especially anthropology (also an interest of some proponents of the sentiments approach), with its comparative study of social relationships and the life cycle of the family. In essence, the household economics approach is concerned with the ways in which the members of the family or household interact with one another in an economic context. Objects of study include relations between husband and wife, master–servant relations (if servants are present in the household), and parental control over the labour of children. Inheritance of property, succession to titles of nobility, and rights to membership in wider family and kin groupings are also areas of special interest, as is the place of the household within the economic life of the community.

While the three approaches outlined above are in many ways complementary, the household economics approach is of the greatest utility for the study of family history from the earliest written records. The sentiments and demographic approaches developed primarily with reference to the history of the Western family since the 16th century, because data useful to these approaches are extremely difficult to obtain from before that time. The household economics approach, therefore, is the main one taken in this article to outline the history of the family in western Europe.

HISTORY OF THE FAMILY IN WESTERN EUROPE

The family in classical antiquity. Within the ancient Greek city-states, four levels of kin grouping could be distinguished: the phratry (*phratra*), the aristocratic clan (*genos*), the kindred (*anchisteis*), and the household (*oikos*). The phratries were large tribal subdivisions consisting of households or families claiming a common kin relation. At the apex of each phratry were aristocratic clans that had certain hereditary rights, such as the right to hold priestly offices. Both the phratries and the clans were recruited patrilineally (through the father).

The kindreds, on the other hand, consisted of a set of relatives from each side of the family, extending at least to the second cousins of any given individual. A person's kindred was important, as this was the unit within which inheritance could be claimed, but the significance of the kindred varied from city-state to city-state and through history. For example, during the 5th and 4th centuries BC such ties of kinship were less important in urban Athens than elsewhere, because of increasing urbanization and the large number of noncitizens in the population. Since in theory only citizens could contract legal marriages and produce legitimate children, the large number of common-law marriages between citizens and noncitizens (and attempts to pass off the offspring as legitimate) led, in classical Athens, to the dissolution of kindred ties that had previously been close.

The organization of the household also varied from place to place and through history. From the time of the Homeric poems (before 700 BC) it seems that the primary unit of residence and domestic economy was the nuclear family (husband, wife, and children). However, a belief in earlier extended-family organization is implied in the *Iliad* and *Odyssey* by the archaic kinship terms employed for relatives of a king and by descriptions of such large extended families as those of Zeus on Mount Olympus and of Priam, king of Troy. In the Homeric world the household was the seat of a person's prestige and a political unit through which alliances were made and struggles for dominance played out.

The rise of the household

As political institutions developed and replaced the household as the seat of power and intrigue, the household became a more private place. The development of the city-states, and especially of Athens, tended to separate public and private life in a way that had not been common before. Public life in the Athenian democracy was characterized by equality among fellow citizens but, at the same time, by an impersonal and competitive attitude toward one another as well as toward noncitizens. Private life (within the household) was characterized by hierarchy, intimacy, and support. The household was hierarchical in that it was headed by a man who held authority over his wife and children and his servants. The ancient Greek household was the key unit of economic relations, too—as is implied in the modern English word economics, from the Greek *oikonomia,* meaning "household management."

The English word family is derived from the Latin word *familia,* meaning "household," and ultimately from the Latin *famulus,* "servant." As it was among the Greeks, the household among the Romans was a significant economic unit within a system of wider kinship ties. The patrilineal kin group or clan among the Romans was termed the gens (plural, gentes). For the aristocratic Roman, this level was more important than was the phratry or clan among the Greek aristocracy, and together the gens and the household were primary focal points of life in ancient Roman society.

The Roman gens comprised a group of kinsmen who bore a common gens name, inherited in the male line by both males and females. In the earliest times, each gens had one or more recognized chiefs. The gentes themselves were grouped into larger units, each known as a curia (roughly equivalent to the Greek phratry), and, above that level, into "tribes," though the significance of these units declined after the formation of the Roman republic in 509 BC. According to custom, each gens shared common property, which included a burial ground and other lands. Property was inherited within the gens, and gens members could call upon one another for help in defending their individual property and for the redress of injuries. It was also forbidden for people to marry within their own gens. Although in theory the gens was patrilineal, under certain conditions and with the consent of the gens as a whole, outsiders, such as kinsmen related other than through the male line, could be adopted into the gens.

Importance of the agnatic (male) line

Whereas the gens as a corporate group was important, especially in the early days of the Roman state (later being important only for aristocrats), descent in the male line was recognized as a significant legal principle by both commoners and aristocrats throughout Roman history. The Romans distinguished two kinds of blood relatives: agnates and cognates. An agnate (Latin *agnatus*) was a relative related through the male line, including one's father's father, father's brothers and sisters, father, brothers, sisters, children (of a man but not of a woman), brothers' children, sons' children, and some more distant relatives. A cognate (*cognatus*) was any other blood relative. Even Romans who did not belong to an aristocratic gens distinguished their cognates from their agnates. Agnates were reckoned to be "closer," because private property was inherited by them and marriage was forbidden between them.

The medieval family. The medieval European family was a product of diverse origins and influences. The family and kinship customs of the Germanic tribesmen, the legal system inherited to a large extent from the Romans, the ideals of Christianity and dominance of the church, and the emergence of feudalism all played a part in shaping the European family of the medieval and postmedieval periods.

The countries of the eastern Mediterranean retained the ideals of patrilineal descent to a greater extent and for much longer than those to the west, where an emphasis on bilateral descent (equal reckoning of kinship from both sides of the family) replaced the more formal structure of the Roman gentes. In northern Europe the Germanic and probably also the Celtic tribes were organized largely on a bilateral basis. Membership in the kin group could be achieved through either one's father or one's mother. The ancient clans of the Irish and Scots, for example, were actually almost tribes, with marriage permitted inside or outside the clan and membership often being determined by residence rather than strictly by descent. Marriage, in fact, was permitted to close kin among the pre-Christian Germanic tribesmen, a practice that no doubt reinforced family ties. Among the Germanic tribesmen monogamy was the norm, but concubines were also permitted.

With the spread of Christianity, close kin marriage came to be forbidden, under penalty of slavery, though concubinage continued for several centuries. (Though they were not allowed to marry, even priests openly took concubines and raised families.) From the 4th century, close kin forbidden as spouses included first cousins, certain relatives through marriage, and even "fictive" kin such as godchildren. In the 11th century the prohibitions were extended yet further, though they were contracted again in the 13th century. Divorce, which had been permitted by the Greeks, the Romans, and the tribesmen of northern Europe, also came to be forbidden or, initially, at least made extremely difficult.

Breaking up the kin group

Of all these changes, the prohibition on close kin marriage was perhaps the most significant. Both St. Augustine and St. Thomas Aquinas argued that marriage outside the group increased kinship ties between communities, thus breaking down the undesirable solidarity of close-knit groups. The church, in a sense, broke the authority of the extended family and kin group. Marriage outside the group also tended to disperse rather than concentrate inherited property and thereby lessened the power and influence of kin-based groups. It is difficult to determine whether these reforms were introduced with the intention of decreasing the authority of families and close-knit communities in preference to the authority of the church or whether this consequence was merely coincidental. Certainly they were not specifically justified on scriptural grounds. Whatever their reason, the changes in marriage prohibitions dramatically altered the nature of the family in much of western Europe, changing it from an extended and essentially self-contained unit with authority over its own members to a smaller, nuclear unit ceding much of its former authority to the church.

Emergence of the nuclear family

Another long-term effect of the decrease in the solidarity of larger kin groups was the increase in importance of the conjugal bond, which in the Middle Ages replaced the large kin group as the focus of familial ties. Here, too, the church was a major force in change, for example, in requiring that those who were to be married consent to the union. Thus, marriage arrangements could not rest solely in the hands of household heads, although marriage was certainly much more a matter for the family as a whole than it is in modern Europe. A gradual change toward the modern family took place in the late Middle Ages, with women and children being recognized as having rights of their own, independent of the head of the household, and with the emergence of the nuclear family or small, core kin group as the basic unit of both production and social life. (The Black Death, which killed about a third of the inhabitants of Europe between 1347 and 1351, may also have been a factor, but recent research suggests that family practices were much less affected by the Black Death than were other social institutions. In fact, changes toward nuclear family organization had taken place in northern Europe long before the 14th century.)

Accompanying these changes was a change in custom regarding the transfer of property at marriage. The Germanic peoples had a custom of paying bridewealth, livestock and other goods transferred at marriage from the bridegroom and his family to the family of the bride. This practice occurred in much of Europe through the Middle Ages, but toward the end of this period there was a marked trend instead toward dowry, payment from the bride's family to the groom for the upkeep of his new spouse. In some cases both kinds of payment existed simultaneously. The reasons for the shift in emphasis are a matter of debate among historians and are no doubt related in complex ways to other social trends in the organization of the domestic economy and of society in general.

The family since 1500. Changes in the family that were set in motion in medieval times continued through the Renaissance and Reformation. The conjugal bond remained important. The question of how much affection existed between husbands and wives has been the subject of much speculation, especially among those social historians who favour the sentiments approach. The British historian Lawrence Stone suggested that the degree of affection in the 16th and early 17th centuries was very limited, but other writers have been critical of this view. The upper-class domestic unit, in fact, seems to have been a close-knit one, but adequate data on the lower classes is extremely hard to find.

Marriage between cousins

One consequence of the Reformation was a reduction in the strictness of rules regarding the marriage of kin, at least in most Protestant countries. The case of England's King Henry VIII is a famous example. He legalized marriage to first cousins so that he could marry Catherine Howard, who was in fact his "first cousin" by marriage, being the true first cousin (in the modern sense of a blood relative) to one of his previous wives, Anne Boleyn. Martin Luther, on the other hand, argued against close kin marriage, not because he believed it was against God's will, but because he was afraid that people would marry in order to keep property within the family, rather than for love.

Sociologists used to assume that before the Industrial Revolution the most common type of family organization in European society was that of the large extended family, with as many as three generations sharing a common household. However, detailed historical studies made in the 1970s and '80s from documentary sources have revealed that the nuclear family was the primary unit over much of northwestern Europe even before industrialization. In fact, Anderson's study of the English town of Preston suggests that the Industrial Revolution, and its consequent urbanization and urban employment, increased the importance of relatives beyond the nuclear family, since the changes taking place enabled individuals to receive help from their kinsmen in times of hardship. In general, in 19th-century Europe, North America, and other parts of the industrialized world, family organization was based on a wider range of social interaction than was usual by the late 20th century. Since marriage was relatively late and life expectancy relatively short, children often remained at home throughout the lifetimes of their parents. Families were large, and older children took part in raising and teaching their younger brothers and sisters. Only in the 20th century has it become common for parents to be left alone in the household in middle age.

In the United States there was an increased tendency toward earlier marriage for both sexes between 1900 and 1960. Since about 1960, however, this trend has reversed. Similar trends have occurred, though generally later, in the United Kingdom and other Western countries. A number of factors seem to be involved in this trend toward later marriage. One is greater economic security. Another is the greater availability of birth control devices, and especially the birth control pill, since the 1960s. This has enabled couples to engage in sexual intercourse with less fear of having unwanted children. Whether the practice of birth control has been a cause or a result of greater permissiveness is not easy to determine, but certainly greater sexual freedom without the social stigma formerly attached to premarital intercourse is another factor in the trend toward later marriage.

Increase in age of marriage

There have long been differences between social classes in the customary age at which people marry. Generally, since 1900, those from lower socioeconomic backgrounds have married earlier. The reason usually given for this fact is that people prefer to marry after their education has ended and they have secured suitable employment. Middle- and upper-class people tend to be engaged in full-time education for a longer time, and career aspirations may outweigh the importance of marriage. In some lower-class households, where marriage itself may be a person's greatest aspiration, this is less likely to be the case. As women achieve educational standards equal to those of men and enter the job market on the same footing, they tend to regard marriage as something to be delayed until "the right time," just as men do. The increase in educational opportunities for people of both sexes since World War II may be an additional factor in the increase in the age of marriage in all social classes within Western societies.

The modern family

There is no precise distinction between modern and premodern families. Some authorities consider the modern family to be identical with the Western family since the Industrial Revolution. Others take the notion of modern in a more literal sense, meaning the family as it is today in any part of the world. Certainly there is no reason to exclude the entire Third World and equate modern only with Western society.

Yet too precise a definition is a hindrance rather than a help. In different contexts the word modern means subtly different things. Its definition depends on the contrasts and comparisons to be made. For the purposes of the following discussion, the "modern family" may be taken generally to refer to family organization as it has existed since the early 20th century. Special concern is directed, mainly but by no means exclusively, toward family organization in Western societies. Even so, cultural, subcultural, religious, and class differences create a variety of forms within the modern family, and this variety cannot be overestimated.

THE FAMILY CYCLE

Courtship and mate selection. In most societies adolescence is marked by social as well as biologic changes. Such social changes often include a new, more formal attitude toward parents and, more particularly, toward members of the opposite sex. In many societies the custom is for young people in the early stages of adolescence to spend time in same-sex groups. Boys may attend sporting events, and girls, overnight parties. Eventually the same-sex groups come into contact with similar groups of the opposite sex at social occasions. In some societies young people go out with mixed-sex groups before they begin dating, but in other countries the practice of dating emerges from the same-sex group phase, as individual young people meet and pair off.

Social aspects of sexual awakening

Often dating is followed by a stage of "steady dating," in which a couple agree to date only each other, and their exclusive dating relationship may become recognized by their peer group and others, including their respective parents. If the couple gets along well together, the phase sometimes defined as courtship may begin.

In its strictest sense courtship usually refers to an activity, such as dating, with intent to marry. Prior to the 20th century, and still today in some societies, courtship was practiced without dating in the modern sense. A young man might visit his intended bride in her parental home and bring gifts, discuss common interests, and perhaps go for walks. To nontraditional people these customs, if continued to courtship, may seem ridiculously old-fashioned, and it is frequently difficult in the modern era to make meaningful distinctions between "going out," dating, and courting. The distinctions are further blurred by modern couples' living together, either before marriage or with no intention of ever marrying.

More typically, though, the family begins with marriage, which grows out of courtship and is preceded by what sociologists call mate selection. Mate selection may be defined simply as the process, often unconscious, of choosing a mate. Usually the mate is the person's intended spouse, and the traditional definition of the term has this implication. Individuals often claim that their match is made on the basis of love, but statistical studies show that other factors are involved. For example, people usually marry within their social class and often to those of the same ethnic group or religion. This practice of like marrying like is known as homogamy. Mate selection is also frequently related to economic factors. For instance, before she will consent to marry him, a woman may want her intended husband to show that he is capable of supporting her.

Homogamy: Cupid and statistics

Betrothal stage. Betrothal may be defined as the recognition by both parties of their intent to marry. It implies a mutual obligation to marry, and it sometimes involves a formal contract between the respective families of the couple. Often an engagement ring, marking this obligation, is given by the man to his intended bride. The ring not only signifies their intent but also publicly identifies the couple—particularly the woman who wears the ring—as intended spouses, warning off other potential suitors. Traditionally, a woman wears her engagement ring with great pride. Yet perhaps because of the inequality in the signification of the event (the fact that, usually, only the woman wears a ring), the custom of giving and receiving such a ring is less common than it used to be.

Just as it has become difficult to draw the boundary between dating and courtship, so too it is sometimes difficult to draw a rigid distinction between courtship and betrothal. A couple may live together for a number of years before deciding to marry, and the betrothal stage and even the marriage itself may thus be reduced from its traditional significance. This is especially true in Western societies, particularly for young middle-class couples. The decline in importance of betrothal is linked to the greater degree of sexual freedom permitted in many societies today. Previously, betrothal often allowed a couple to engage in sexual activities not permitted between those who were merely dating or courting. Even where sexual intercourse was prohibited before marriage, other forms of sexual license or nonsexual intimacy were permitted. In parts of Scotland and Scandinavia, for example, engaged couples were allowed to sleep in the same bed but were sewn up in different sleeping bags, a custom known as "bundling."

Decline of betrothal

Marriage stage. Marriage is frequently regarded as the most important event in a person's life. It is also a significant event in the family cycle, both for the families of the bride and groom and for the new family formed by the union itself. For young people, marriage often marks a break with the authority of their parents (who, together with brothers and sisters, are known as the "family of orientation"), and it is simultaneously a key step in the formation of a new family (the "family of procreation"). The couple must learn to live together and work out their own changing social roles within the context of the marital unit. Thus, though marriage often represents a break with parental authority, it also involves a sacrifice of independence. Husbands and wives must compromise with each other and learn to make decisions, not alone, as they had done when single, but together. Perhaps not surprisingly, those who marry for the first time relatively late in life often retain more individualism than those who marry early. Such people may maintain a greater degree of social independence and at the same time develop successful marital and family relationships.

In the early period of marriage, husbands and wives tend to spend a great deal of time with each other. It is traditional in some societies for a husband or wife to have a "night out," perhaps once a week, with other people of the same sex and without the company of the spouse. The rest of the week, except for working hours, they generally spend together. This time together, especially if begun at a relatively early age, leads to unconscious learning and acceptance of each other's habits and idiosyncracies.

Marriage is usually marked by a sharp increase in sexual activity. Sexual access is obviously easier for a married couple living together than for most single people, who tend to live apart from their partners. For many people, for reasons of religion or morality, sexual intercourse is permissible only after marriage. For others, marriage simply makes sexual activity more convenient.

Social status of marriage

Marriage also marks a change in social relations with others. Whereas before marriage people interact in most social spheres as individuals, after marriage there is a tendency for the married couple to be the primary unit in social activities. Invitations to parties, for example, are made to a couple, not to one partner only (though this may also be true of engaged or courting couples). The couple may come to be seen as an inseparable unit, thus marking the marital unit as a "corporate" entity. Recognition of this status also paves the way for the recognition of the role of the marital unit in its ultimate capacity as a family of procreation.

Children. For most people, children are the key to a happy family life. They are also integral to the definition of family life, and many sociologists regard the raising of children as the primary function of the family.

Childbirth, of course, is a biologic fact, but it is equally a social phenomenon. It requires a readjustment of roles as people become not only husband and wife to each other but also parents to the newborn child. The birth of subsequent children can have equally considerable restructuring effects on the family, including a change in roles for the older children. Relations between the new parents and their own parents are often heightened as the latter take on their new roles as grandparents. In many societies, grandparents are indulgent toward their grandchildren, while the parents themselves may be required by convention, and some would say by necessity, to be stricter.

The specific social adjustments people must make after the birth of a child differ according to individual circumstances and cultural attitude. No matter what pattern is followed, however, ideally the children are brought up to become productive members of their society. To achieve this, they must acquire education within the family and, later, within the institutions of the society as a whole.

Child rearing and socialization. The American sociologist Talcott Parsons believed that the two most important functions of the modern family are the primary socialization of children and the stabilization of adult personalities through marriage and the raising of children. His own concern was particularly with the middle-class American family, but these important aspects of family life are also applicable much more widely. In the present context it is worthwhile to look especially at primary socialization.

Primary socialization refers to the training of children during their earliest years, whereas secondary socialization refers to later influences on the development of the child's personality and learning activities, such as his involvement with teachers and with other children at school. Primary socialization is in most societies carried out essentially within the family as part of child rearing. In the modern family, parents take responsibility for raising and teaching their children such basic things as language and correct behaviour. Toilet training, teaching children how to eat correctly, and encouraging children to get along with others are all aspects of child rearing. However, it is not only these more mundane aspects of behaviour that children learn. Children are also implicitly encouraged to develop the values of the parents and of the society in which they live. In American society, which was Parsons' main concern, these values include independence, motivation for achievement, and competition. In other societies, different values, such as cooperation and egalitarianism, may be stressed. Yet the principle behind primary socialization in different societies is the same: the development of social values must be achieved in an environment of love and security, as is found in the ideal family anywhere in the world.

The child as scapegoat

Few families are ideal, however. Studies of the families of emotionally disturbed children have shown that unsatisfactory relationships between husbands and wives can have detrimental effects on children. Sometimes a child is used as a scapegoat. The parents blame or even physically abuse the child in order to cover up their own difficulties. In such a case, the child often fails to develop the values the parents wish to instill in him, developing instead antisocial habits leading to deviant behaviour in later life. Indeed, the cycle may be repeated if such a person in time marries, has a family of his own, and treats his children in the same way. Nonetheless, there is no reason to suppose that all children of unsatisfactory marriages are treated in such a way or fail to overcome the difficulties they have as children.

Some social scientists have even suggested that the isolated nuclear family, as it exists in Western industrialized societies, is to blame for the social ills found in those societies. They claim that in the past more support was offered from the wider kin network and from the community as a whole—as is still the case in less-developed parts of the world. The British psychiatrists R.D. Laing and David Cooper suggested that the modern family is dysfunctional in that, by its very nature, it forces upon children an undue emphasis on obedience to authority. These negative viewpoints aside, most experts as well as most parents agree that the primary socialization process in the modern family offers benefits both to the child and to the parents.

Middle age. As the children grow up, the family undergoes certain changes. Parental roles shift from child rearing and socialization to financial maintenance coupled with keeping a watchful eye on the children's school and social activities and preparing them for adulthood.

Middle age is generally considered to be the stage in the life cycle when parents finally achieve a degree of independence, from both the burdens and the delights of raising children. At this stage in the life cycle, marriage often comes under strain. As in the earliest stage of marriage, the couple may find themselves alone with each other. For many it is a period of crisis, since it involves a change in roles. This may have advantages. The husband and wife can travel more freely or go out more often without worrying about their children. They may have greater financial independence if their wages or salaries are higher than in their younger days and if they do not have to spend as much money on their children, who, by this stage, probably have jobs of their own.

Readjustments of middle age

On the other hand, middle age is coupled with physiological changes that can cause health problems or simply a feeling that life is passing by. Women who have taken primary responsibility for raising their children may feel a loss at their departure. The same may apply to men, of course, but usually not to the same degree. New relationships are formed with children-in-law, and it is often difficult for parents to adjust to the fact that their children share their love with their own spouses as well as with the parents. (Mother-in-law jokes are found throughout the world and have much basis in fact.) In addition, both men and women may feel a loss in confidence owing to the feeling that they are no longer as sexually attractive as they once were. This too may put strains on the marital bond and cause partners to stray.

Old age: children caring for parents. A precise distinction between middle age and old age is virtually impossible to draw. Certainly retirement marks a commonly recognized point of transition for many people, though they may not wish to consider this as the beginning of old age. Within the family a key factor, equally important, is the stage at which the parent–child roles are reversed, when children express their concern for the well-being of their parents by providing emotional or financial support. Often a parent, after the death of a spouse, comes to live with one of the children. Sometimes a child who has become successful provides money for the upkeep of the parents, or surviving parent, even if living elsewhere.

The transition to old age is, of course, not necessarily abrupt and does not necessarily lead to a feeling of alienation, as was once supposed. On the contrary, several sociological studies, notably in the United States, the United Kingdom, and Denmark, have shown that most old people have at least one child living nearby, often only a few minutes' traveling time away. In many Third World countries, where it is customary for parents and children to reside in the same village, if not in the same household, contact between children and elderly parents is even greater. In both traditional and modern cultures, adult children take great responsibility for the welfare of their aged parents. This is true not only in rural areas but also in urban ones, and for all social classes.

Death and bereavement. The death of a family member affects not only the individuals in the family but also the family unit collectively. The precise difficulties the family faces and the manner in which they cope with them depend on particular circumstances. Nevertheless, a few generalizations can be made with respect to the kinds of problems that frequently develop.

For the family as a whole, one obvious effect is the disruption of normal activities. This in turn may lead to the surviving family members' gaining greater resolve to face up to their loss collectively. On the other hand, it may lead instead to fragmentation similar to that which follows divorce. Indeed, divorce and death often have similar effects on children. Removal of an authority figure may lead them to take on greater responsibilities in the family, or greater independence, or it may lead instead to family conflicts and a lack of family solidarity. It may also break the remaining ties between brothers and sisters who live apart.

Losing a partner

Bereavement has a profound and more individual effect, too, on the surviving spouse. This might be enhanced if the couple were married for most of their lives and particularly if they shared their last years together in isolation from their children. Studies in the United States have shown that, in general, a husband who survives the death of his wife has greater difficulty in coping than a wife who survives the death of her husband. Not only does a surviving husband have to cope with emotional loss but he also has to take on tasks such as cleaning and cooking—which in many modern societies are still usually done by the wife. On the other hand, some sociologists have argued the reverse, that a surviving wife has greater difficulty, owing in part to the larger number of women who live to an advanced age and the resulting greater difficulty they have in finding a new husband. In other societies, such as India, widows are given distinctly inferior social status to married women and have a much harder time than widows in the West. In most parts of India widows are not permitted to wear brightly coloured clothes or to look after their appearance, and attendance at certain rituals, notably weddings, is forbidden them. Indeed, it has been suggested that the practice of suttee (immolation of the widow), formerly practiced in India, was in part encouraged by the extreme hardships that faced widows in medieval Hindu society.

MARRIAGE IN MODERN SOCIETY

Legal aspects of marriage. In nearly all cultures, marriage is distinguished from courtship or living together out of wedlock by a ceremony or series of ceremonies. These often involve bridewealth, dowry, or simply the giving of gifts, by anyone, to the newlyweds. Wedding ceremonies may be civil, religious, or a combination of the two. In Great Britain, for example, those who marry in a church must undergo a short civil ceremony (the "signing of the register") at the end of their wedding in order to validate the religious ceremony in the eyes of the state. For couples who include a divorced partner, the reverse is sometimes true: the couple may undergo a religious ceremony, in which they repeat their wedding vows, in order to receive full recognition by the Church of England of the civil ceremony they have previously undergone.

Legitimation of offspring

The main purpose of the legal validation of marriage in almost every society is to provide for the legitimacy of children. Marriage in most societies is required by custom in order to give children legal recognition as members of a family or wider kinship group and to allow them to inherit property from both parents. In some modern societies, natural children born to parents living out of wedlock are also given these rights, usually upon petition in the courts, but the norm is that the right of a child to inheritance is defined by the marriage of his parents. This is even more true when it comes to succession to titles of nobility in the male line or membership in patrilineal kin groups. Without marriage, the child belongs to the mother alone and is ineligible to inherit a title or membership in a kin group. In Western society these legal requirements date back at least to Roman times, and similar rules, distinguishing the children of wives from those of concubines, were also found in biblical times.

Marital roles. Marriage is important as the accepted institution for the expression of adult sexuality. A mutually satisfying sex life is important to both men and women, although social scientists point out that marital roles involve much more than this. Romantic love is only one of the reasons people marry. Social and economic security, and indeed social pressures, can be equally important.

The "macho" image

Relations between the sexes are to a large extent culturally as well as biologically determined. The image of the "macho" male is well-known and attributed commonly to Mediterranean and Latin-American cultures. In working-class British culture, too, tenderness in a sexual relationship has been traditionally regarded as unmanly. The public image that such men wish to project is based on sexual prowess rather than on emotional intimacy. This image may even be retained after marriage if manliness is defined by how completely a man can rule his household.

In the past, women frequently took their social status from their husbands, but by the late 20th century there was an increasing tendency for women to be regarded as equal partners in marriage. The traditional norm, where women remained at home and men went out to work, has changed rapidly. As women gain status from their own occupations outside the home, they are beginning to achieve equality with men. Women's traditional sphere of influence has been the home, however, and in cultures as diverse as the Khoikhoin (Hottentots) of southern Africa and sections of the working-class population of modern Britain, women's economic authority in the home remains paramount. Even today it is not uncommon for the British husband to depend on his wife to give him spending money, even though it may originate in his wages.

Trend toward the "symmetrical family"

In a study of the family in a low-income area of London, British sociologists Michael Young and Peter Willmott found that what had previously been regarded as the typical late 19th-century family had survived into the 1950s. This type of family was centred on the economic separation of the roles of husband and wife, sometimes with both partners working and frequently with the wife sharing domestic tasks with female relatives who lived nearby. Young married women, for example, received help from their mothers in shopping, household chores, and babysitting. In further studies made in the 1970s, however, Young and Willmott documented changes toward what they called the "symmetrical family," in which kin networks had ceased to be as extensive as in the past and husbands and wives shared domestic tasks between them. Social activities, too, had become more couple-centred, as in many cases men stayed home, perhaps to watch television, rather than to socialize with their male friends. In short, at least in London, there was a development of working-class marital roles toward a pattern similar to that found in most middle-class households. Indications are that the trend is a widespread one.

Parental roles. In all societies, past and present, parents have played a major part in caring for children. Modern parents retain the vestiges of their traditional roles, but in many parts of the world they send children to nursery school, kindergarten, and then to school, thus delegating to teachers some of their traditional responsibilities for the socialization of their children. In Western societies there is a tendency toward social equality. Wealthy parents rely less than in the past on nannies to raise their children, and lower- and middle-class parents have greater access to preschool facilities than formerly. As with marital roles, there seems to be a trend toward the reduction of differences in parental roles among social classes. The trends may indeed be related. In the non-Western world, too, modernization and economic development similar to that which took place in Europe during the Industrial Revolution are now creating a situation of greater freedom and responsibility for children. The temporary absence of fathers who take jobs as migrant labourers, for example, may place teenage children in a position of responsibility over their families. At the same time, other young people in these countries often seek employment and independence in urban areas.

Paradoxically, however, from a child's point of view, Western parents are often regarded as inhibiting independence, particularly during adolescence. In most modern societies, parents show an interest in and concern for the sexual activities of their children, something they do not do in most "primitive" societies. In modern Islāmic societies and in modern India, as in some other parts of the world, parents have the duty to ensure that their children find suitable wives or husbands, and even the children recognize this. Yet in modern Western societies the practice of parental matchmaking is regarded by children as interference in their affairs. Even before marriage, they begin to assert their independence, which, arguably, was instilled in them by their parents themselves in the socialization process.

Unequal marital roles

Feminist perspectives. One effect of the feminist movement has been an increase in sociological studies directed specifically at the roles of women in society in general and in the family and marriage in particular. The American sociologist Jessie Bernard, for instance, argued that the study of marriage must focus both on husbands' and on wives' expectations and achievements. She noted that married men are generally more successful than single men in achieving their goals in life, whereas the opposite is true for modern married and unmarried women. This view contradicts that of Young and Willmott, who saw the modern symmetrical family as a step toward greater equality and similarity of roles between husband and wife. Much of the data Bernard cited was psychological: American wives are known to be much more prone to anxiety and depression than their husbands, and this, she argued, reflects the unfairness in marital roles as conceived in American society.

Ann Oakley made a similar case for Britain. She examined the changing roles of women since the Industrial Revolution and, in particular, the emergence of a new status of woman as housewife. Oakley, and many others in feminist circles, have regarded the role of housewife as degrading to women in that it prevents them from achieving economic and social independence on the same basis as men.

Another effect of the feminist movement has been a greater awareness in society as a whole of a double standard in sexual behaviour and a growing feeling that such a standard is unfair to women. Under this code of conduct it is permissible for men to engage in premarital and, to some extent, even extramarital sexual intercourse, while women are expected to remain chaste before marriage and faithful to their husbands afterward. This double standard and its inherent assumption of sexual inequality is a cause of concern for many women.

Separation and divorce. In most societies, it is possible to end marriage through divorce. Even where divorce is not permitted, separation may be allowed, either on a de facto basis or as a legally defined status. In many Western countries, marital separation is often thought to be a relatively new problem. Certainly divorce was much more difficult, for example, in early 19th-century England (when it required an act of Parliament for each divorce granted) than it is in England today.

Religion and divorce

Religion is a major factor governing the availability of divorce. In some religions, such as Islām, marriage is regarded as a contract between two parties rather than as a union intended for life and blessed by God; the Qur'ān states that it is better to divorce than to live in an unhappy marriage, and in Islām divorce is available to the man simply by the repetition of a verbal formula three times. In many Christian countries—in particular, Roman Catholic countries—divorce is difficult to obtain. Marriage is regarded by the church as ordained by God and thus as indissoluble. In Italy, for example, divorce has been permitted by law since 1970, but the church does not recognize the legitimacy of civil divorce. Thus, couples frequently separate and live apart. In fact, five years of continued separation are required before a civil divorce can be granted, and even after this period couples do not necessarily obtain a divorce. In the Orthodox churches, divorce is permitted, but, as in Roman Catholic countries, divorces granted in civil courts are not necessarily recognized by the church. Thus, in countries such as Greece or Russia or among members of the Orthodox faith in emigrant communities, couples must seek separate divorces from the church independently of civil divorces granted by government authorities.

The frequency of divorce. Divorce rates have markedly increased in many countries since World War II and in some countries have been on the increase since the early 20th century. Attitudes toward divorce have changed dramatically in this period, with the general trend toward tolerance of the practice. Although the statistics are highly variable for overall rates, a number of correlations can be drawn between divorce and other factors.

First, divorce rates are affected by national conditions. Historical studies have shown that, in general, fewer divorces occur in times of economic depression and more in times of prosperity or war. The frequency of divorce in the United States, for example, nearly doubled during World War II.

Second, divorce rates are affected by factors related to social circumstances, including ethnic group, religion, class, and economic background. Divorce rates can be expected to be higher in groups that attach less stigma to divorce than in those that attach more. The backgrounds of partners have a more complicated effect on divorce. Studies of racially mixed marriages, for example, show that these may yield specific patterns within specific cultures. One study in the United States suggested far greater stability in marriages of black husbands and white wives than of white husbands and black wives. Such differences no doubt depend on factors derived from sex roles in American society generally, or they may be related to the kinds of people who are most likely to marry outside their group.

Third, divorce rates vary according to the family cycle itself. Many studies have pointed to the fact that the longer a couple has been married, the more likely it is to remain so. Divorce rates are highest among the young, and, if a marriage survives its first few years, there is an increased likelihood that it will continue. Another factor often cited is the presence of children as a deterrent to divorce. Empirical studies have shown, however, that this factor is much less significant than commonly believed.

Divorce and remarriage

Remarriage. With the trend toward higher divorce rates has come an increase in the number of people marrying for the second, third, or fourth time. For most people, including those who have been divorced as well as those who have not, marriage is regarded as the normal way of life. People who have been divorced at least once and have then remarried, however, have a higher probability than others to be divorced again. This tendency may reflect attitudes that result from earlier experiences, but it may also reflect the possibility that a certain proportion of the population finds it especially difficult to maintain long-term relationships. Internal psychological makeup is sometimes responsible, but factors such as occupation and lifestyle are at least as important.

EXPANDING THE BIOLOGIC FAMILY

In many traditional societies, the more children a couple has, the better off is the family. Children have been valued both in their own right and for the labour they perform. In many modern societies, too, there remains a great desire to have children. While modern birth-control methods allow many couples to limit the size of their families, modern advances in medical technology enable those who cannot produce children naturally to do so artificially. At the same time, the legal mechanisms of fostering and adoption offer traditional alternatives for expansion of the family beyond biologic children.

Artificial insemination. While many couples use birth control to limit the number of children, others have taken advantage of changing mores and new technology to increase their chances of having children. One method is artificial insemination, which involves the implanting of semen into a woman's uterus by means other than sexual intercourse. The semen may come from the woman's husband or, if the husband is sterile or is suspected of carrying a hereditary disease, from a (usually anonymous) donor. Artificial insemination by donor, although still rare, is becoming more common and socially acceptable. Nevertheless, for many people there are moral or legal complications.

Many modern Western legal systems fail to distinguish the pater (social father) from the genitor (presumed biologic father), while most traditional societies do make the distinction. Where it is not made, the law may regard the semen donor as the "father" of a child produced by artificial insemination and oblige him to bear financial responsibility for the child. Artificial insemination is even regarded by some people as a form of adultery. In order to prevent such difficulties, clinics that perform the insemination keep the identity of donors secret. Often they also mix donated semen with the semen of the prospective social father, in order to preserve the legal fiction that the pater and genitor are the same man.

Surrogate motherhood. The late 1970s saw the birth of the first "test tube babies," conceived in vitro ("in glass") under laboratory conditions. In vitro fertilization normally begins with the extraction of an ovum, or egg, and the fertilization of the ovum in a laboratory dish. The fertilized ovum is then introduced into the uterus, where it develops normally. In itself, in vitro fertilization is not particularly problematic, since it can and often does involve simply fertilizing an ovum from the woman who will carry the child. It becomes problematic, however, when the woman is a surrogate mother.

Problems of surrogacy

A surrogate mother is a woman who carries a child on behalf of another woman, who will become the child's social mother. The social mother will also be the child's genetic mother if she donates the ovum. The problem is that three roles normally borne by one woman—genetic mother, childbearing mother, and social mother—are now divided between two. In addition, the sperm may come from the husband of one of the women or from another man. Because of these complications and the emotional strain on both mothers (and potentially the child), surrogacy has been made illegal in some countries. In others, it is becoming institutionalized, and laws are being changed in order to define precisely the rights and obligations of parents and children in this situation.

Fostering. Fostering is the practice of using a parent or set of parents to care for someone else's child on a long-term basis. Often the child's own parents have died or have been declared legally unfit to look after him. Modern government social services and some private agencies place such children with families they believe will give them good homes.

Adoption. Fostering is often a first step toward adoption. Although both practices involve the assumption of parental roles by persons who are not the child's biologic parents, adoption involves legal considerations not found in fostering.

The original ancient Roman notion of *adoptio,* or "adoption," was simply one of passing legal authority over an individual from one person to another, often for the purpose of making alliances and securing the inheritance of property. In Roman times the person who was adopted was most often an adult male who continued, even after his adoption, to retain ties of love and duty toward his own living parents. In modern society these ties are normally broken in favour of ties of affection between the adoptive parents and children. The modern notion of adoption, then, combines legal aspects of the Roman notion with the affective aspects of both fostering and biologic parentage.

Adopted children in most countries today enjoy the same privileges as natural children. They are treated as fully part of the family into which they are adopted. Adoption gives couples who are unable to produce children of their own the chance to raise children, who might themselves not otherwise find a home.

FORMS OF FAMILY ORGANIZATION

The nuclear family. The nuclear, or conjugal, family is the basic unit of family organization in virtually every society. It is generally defined as a married couple and their children (including adopted and fostered children, as well as the couple's natural children). Other forms of family organization, such as compound and joint families, are in a sense built upon the nuclear family or contain units comparable to it in their structure.

The primary unit of production and consumption

In many modern societies the nuclear family is identical to the typical household unit. Members of the nuclear family share the same dwelling place, usually a single house or apartment. In agricultural societies the nuclear family is often the primary unit of production, sharing tasks and taking collective responsibility for the income that sustains them. In both agricultural and other types of communities, the nuclear family is almost always the primary unit of economic consumption. One or both parents, and sometimes children, earn money outside the home and then share at least some of the fruits of their labour with the family as a whole.

The one-parent family. A common variant of the nuclear family is the one-parent family. This form consists of one parent and his or her children. One-parent families may be formed through widowhood, divorce, or separation. They may also be formed when an unmarried person, usually a woman, raises children on her own. In many Western industrialized societies, the one-parent (especially the single-mother) family is becoming more common and tolerated. However, the extent to which it is as successful as the traditional nuclear family is a matter of conjecture.

In many traditional cultures an unmarried mother is encouraged or even forced to marry, or else she is required to give up her child for adoption by another family. It is becoming increasingly common, however, for a mother to retain her children and raise them, often with the help of her own parents or of government social agencies. In many countries this type of arrangement is more socially acceptable than formerly. In some parts of Africa, for example, female-headed one-parent families are actually more common than nuclear families as the basic household unit.

Sometimes such an arrangement is permanent, but similar female-headed households are also common in places where men are forced to leave their wives in order to find work. In southern Africa migrant labourers often have to leave their families for years at a time. This variant, however, is regarded by many sociologists as a form of nuclear, rather than one-parent, family organization. The man supports his family with wages earned away from his marital home but continues to regard it as his home, even though he may live for extended periods elsewhere. A somewhat different but related form of family organization is the West Indian matrifocal family (see below *Universality of the family*).

The compound family. The compound family is common in many traditional African societies, as well as elsewhere in the world, and is found especially where polygamy is permitted. The compound family consists of a central figure (normally the household head), his or her spouses, sometimes concubines, and their children.

Polygamy

In West Africa, for example, a man may have several wives, with each wife as the head of a subfamily unit composed of herself and her children. The wives may occupy separate dwellings within the same compound or homestead, and they often cooperate in activities such as gardening or in raising children. Children may address each woman as "mother," but they know which is their true mother and to which subfamily they belong. This form of family organization can be seen as an overlapping set of nuclear families, each with the same man as family head. While male-headed compound families are far more common, a female-headed, polyandrous version (one woman married to several men) is traditional among the Todas of South India.

The joint family. A much more common form of family organization, one that is typical in parts of India, is the joint family. In this type, a group of brothers and their wives and children all live together in the same household. In India the joint family may have property held in common by male members of the small, coresident patrilineal kin group, though joint families in other parts of the world (traditionally in China and in parts of Africa) do not necessarily have such collective rights. Sometimes the full joint family is a phase through which nuclear families pass, dividing upon the death of key persons and forming again as men are able to incorporate their sons' wives and children into their own household.

If one person is designated as the family leader and another (normally his eldest son) as his successor, this is often described as a stem family. Such arrangements occurred in feudal Japan, in feudal and postfeudal Europe, and among some groups of immigrant farmers in the United States. Joint and stem families do not have to be based on a patrilineal kin group. Sometimes, especially in Africa, they are composed of people related to one another in various ways, including blood ties through women and ties through marriage.

The extended family. There is no precise distinction between the joint family and the extended family, and the latter term can be used to encompass both. In a narrower sense, sociologists usually think of the extended family as being larger and maintaining less control over its members than does the joint family. In most extended families, the marital bonds between spouses are stronger than the kinship bonds between, for example, the brothers who are the focal people in Indian joint families.

Economic cooperation in extended families

As a household unit, the extended family is most common where ties between kinsmen are important for economic reasons. It was common in Europe during and just after the Industrial Revolution and, more recently, among European immigrant communities outside Europe. It is still common in many parts of the Third World, in both agricultural and industrial contexts, and in Asian communities in the United States, Canada, and Great Britain. Typically, a group of kinsmen live together and share resources. In a traditional context, there may be common property in the form of agricultural lands, livestock, or ritual property such as sacred objects and sacred sites. These last are important in some African societies and among the Australian Aborigines. In modern societies the extended family offers benefits in areas where government agencies have not penetrated or where essential services are not adequate or not provided. Even where there is no common property, members of extended families may draw on one another when they need financial help.

The term extended family also applies to family units that do not establish a single place of residence. The case mentioned above, of working-class people in London who at least into the 1950s shared domestic chores, is one example. The key aspect of the extended family is not that it necessarily shares the same dwelling or place of residence but that relatives give material assistance to one another and share economic responsibilities.

Kin networks. As extended families disperse and government agencies take over economic responsibilities formerly held by them, extended families become kin networks. This has happened in most modern societies. Whereas the extended family is usually associated at least with residential proximity, if not coresidence, kin networks for many people stretch around the world.

An interesting result of worldwide migrations, such as those from Europe during the late 19th and early 20th centuries, or following World War II, has been the extension of kin networks. Far from being dissolved, as some people suppose, these networks often take on a peculiar significance. Many Americans, Australians, New Zealanders, and others keep in contact with their countries of origin in Europe, Asia, and elsewhere. This contact contributes to their personal identity with their countries of origin. Kin networks are often better maintained between dispersed families than between those in closer proximity. Australians, for example, generally know their personal family histories and keep in touch with distant relatives in the British Isles and elsewhere, whereas their British cousins tend to have less interest in these matters and may have less need to keep in touch with relatives within the British Isles.

A less dramatic but equally important form of kin network is that between urban and rural areas within a particular country. As migrations to urban areas have increased, contacts have been kept up, and urban families may keep in touch with relatives in cities other than their own, as well as with relatives in their places of origin. This happens less in Europe, but it remains important in many parts of North and South America, the West Indies, Africa, and Asia.

UNIVERSALITY OF THE FAMILY

Murdock's hypothesis. In 1949 the American anthropologist George Peter Murdock published the results of a major survey of kinship and social organization in a worldwide sample of 250 societies. Murdock's starting point was the family, and on the basis of his survey he argued that the nuclear family is universal, at least as an idealized norm.

Universality of the nuclear family

All of the societies in Murdock's sample exhibited some form of family organization. More specifically, although many societies were organized into polygamous families and extended families, even these had as their basis at least two nuclear families per polygamous or extended family household. The polygamous (compound) family was made up of two or more nuclear families affiliated through plural marriage, while the extended family consisted of two or more nuclear families joined together through parent-child ties. In Murdock's sample, 47 societies had only the nuclear family level, while 53 possessed polygamous but not extended families, 92 had some form of extended (including polygamous-extended) family organization, and the remainder proved impossible to categorize on the basis of information available at the time. Murdock's key point was that, even where complex forms of family organization occur, nuclear families are still found as the basis of the more complex forms.

Murdock argued further that the nuclear family is not only universal but also universally important. Earlier writers had argued that in many tribal societies the nuclear family is insignificant and serves no important functions in the lives of most people. Murdock, in denying this view, pointed out that the key functions of the nuclear family and its universal status are most apparent when viewed in reference to the relationships that make it up. The key functions include the sexual, economic, reproductive, and educational aspects of the family. The relationships include the bonds between husband and wife, father and son, father and daughter, mother and son, mother and daughter, brother and brother, sister and sister, and brother and sister. These eight relationships have come to be known as those of primary kinship, and they are normally the relationships through which all more distant ties of kinship are traced.

The Nāyar case. The Nāyar family evokes interest because it casts doubt on the universality of both the nuclear family and the institution of marriage. The Nāyars are a high-caste group in southwestern India. Modern Nāyar families are not appreciably different from those of other Hindu groups, but before around 1792, when the British assumed control over the area where they live, Nāyar family life was very different.

According to a number of scholars who studied 18th- and 19th-century reports on their social organization, marriage did not exist among the Nāyars, although certain customs that bear a resemblance to aspects of marriage did. In particular, these included the tali-tying ceremony and legitimate unions between a woman and a series of lovers or "husbands" known as *sambandham* partners.

A tali is a gold or silver emblem that, in other parts of India, is tied around a woman's neck by her husband during the wedding ceremony. Among the Nāyars it was tied instead by a man of equal or higher status, sometimes a non-Nāyar, on a Nāyar girl during a ceremony that otherwise resembled more an initiation rite than a marriage. Several girls received talis at the same time. Some Nāyar girls removed their talis soon after the ceremony (which would never be done elsewhere in India), and in no case did the Nāyar tali-tying ceremony imply an enduring sexual relationship between the girl and her tali-tier.

In contrast, the *sambandham* relationship involved no religious ceremony, but it did involve a sexual union. Each woman took a series of partners through her life. She could, in fact, be involved in more than one such relationship at a time. (The explanation for such an arrangement may lie in the fact that the Nāyars were traditionally a warrior caste, women being left alone to look after their households and children while the men went to war.) Apart from gifts to his partners, a man had no obligations within the *sambandham* relationship. His only strong ties were to the family in which he grew up, which included his mother and other relatives related through his mother, such as his sisters and brothers. The father was not socially important, and a man had no obligations toward his children. Nevertheless, he did have obligations, through his female relatives, to a kin group including his mother, mother's mother, mother's siblings, and sisters' children. His responsibilities were to his sisters' children, not his own, and his sisters' *sambandham* partners' responsibilities were to their sisters' children.

It is doubtful that the term nuclear family accurately applies to this arrangement. Some scholars use the term subnuclear family, which retains the notion of family organization, for such an arrangement, and indeed the traditional Nāyar subnuclear family bears some resemblance to the one-parent family in Western society. The Nāyar system can also be regarded as separating the two phases of Hindu marriage and two or more of the roles normally ascribed to a Hindu husband. Among other Hindus (and indeed among the Nāyars today), the tali-tier and the lover are the same person, whereas in the past the Nāyars held these two roles to be distinct.

The West Indian matrifocal family. The West Indian matrifocal family is another well-known form of family organization that casts doubt on the universality of the nuclear family. For many lower-class West Indians, both rural and urban, the role of the father in family life is negligible. The mother is the central figure, hence the term matrifocal (meaning focused on the mother). In the usual pattern a household comes into existence after a man and a woman set up house together. Their cohabitation is sometimes based on a legal marriage, but this is not necessarily the case. When children are born of the union, they are looked after by their mother, who in turn depends on her husband or lover for financial contributions toward running the household.

Minimal role of the husband

What makes the matrifocal family unusual is that the husband takes little or no part in child care and may indeed spend little time at home, often living elsewhere in the same community. Although in other parts of the world such behaviour would be frowned on or even thought of as deviant, in the West Indies it is socially acceptable. Eventually the older children, when they leave school, contribute toward the earnings of the family, and the importance of the father may be reduced even further. From this point on the mother is not only the focus of emotional ties but also the centre of economic and decision-making activities for the family. This is true whether or not her husband or lover is present as a member of the household. Older girls frequently take lovers and have children of their own while still living with the family. These children, in turn, often grow up looking to the focal figure of the family, their maternal grandmother, as the dominant figure in their lives.

The matrifocal family often dissolves with the death of the focal figure. Sometimes a mature daughter, with the help of her father, is able to keep the family together for a time, but this is not usually the case. The brothers and sisters normally move away to set up their own households, and they repeat the cycle with matrifocal families of their own.

This form of family organization, now common in the West Indies, bears no necessary relationship to the family's economic needs, but its origins may ultimately be economic. It has been argued, for example, that the female-headed household is descended from the separation of men from their families during the period of plantation slavery. Another view places the origin of the custom even earlier, in the West African compound family and the practice of polygamy (see above *Forms of family organization*).

The Israeli kibbutz. A kibbutz (plural kibbutzim) is a type of agricultural collective found in Israel. Its typical features include the collective ownership of property, communal living, and the rearing of children by the community as a whole rather than by their parents alone. Although there are differences between kibbutzim, for example, in religious belief or in the degree of social ownership, the structure of kibbutz society in general has frequently been proposed as a counterexample to the view that the nuclear family is universal.

Murdock argued that the nuclear family in all societies performs sexual, reproductive, and economic functions. In the kibbutz it is the case that sexual and reproductive functions are served through marriage. After a period of cohabitation, kibbutz members normally marry under Israeli law, which is necessary in order to grant legal rights to their children. Yet contrary to Murdock's definition, the relationship called "marriage" in many kibbutzim has no economic functions. Economic activities such as working in the fields or with agricultural vehicles, and even activities like sewing, laundering, and cooking, are performed for the whole of the kibbutz. Women do not change their names upon marriage, and they continue to work as before. Meals are taken communally and not in a family unit.

Communal raising of children

Education, too, is often the responsibility of the kibbutz as a whole. But whereas this is true to some extent in all modern societies in which children attend school, the kibbutz takes the principle a step further. In many kibbutzim, children are raised from a young age by nurses and teachers, not by their parents. They eat and sleep in special quarters, not in the marital quarters of their parents. The purpose of these arrangements is to instill in children at a young age the communal values of kibbutz life. One interesting side effect, however, is that children brought up together in the same kibbutz tend to form sexual bonds in later life with people from outside the kibbutz. Members of their own kibbutz are all, in a sense, their "brothers" and "sisters." Similarly, although parents are much more attached to their own offspring than to those of other kibbutz members, they nevertheless refer to all of them as "our children." The structure of kibbutz life thus raises questions about the universality of the family and the psychological and sociological nature of family relations.

The traditional Nāyar family and the West Indian matrifocal family thus represent unusual systems of family organization—not because there are no cases of one-parent families or "uncaring fathers" in other societies, but because in these two systems the idea of a family in which the father plays little or no part is institutionalized as a social norm. Communal families such as the Israeli kibbutz are significant because they deny the importance of the nuclear family within societies in which nuclear families are considered normal and appropriate. Although Murdock's hypothesis may in the strict sense be overturned by these examples, they are nevertheless exceptions proving the rule that in human society the nuclear family is indeed almost universal.

Kinship

Kinship is a socially recognized relationship among people connected by marriage or common ancestry. Kinship systems are universal throughout human society, differing among cultures in their importance in the broader social structure, the number of relatives they include, and the demands they place upon the members.

The study of kinship began in the 19th century with what have been called conjectural histories—attempts by such people as the German Socialist philosopher Friedrich Engels to speculate on the origin and development of kinship systems. In the early 20th century Sigmund Freud expanded his psychoanalytic studies to speculate on the historical roots of the family, and later in the century sociobiologists used genetics and evolutionary theory to the same end.

Engels, Freud, and the sociobiologists are the best-known and among the most dramatic of those who have touched upon the question of kinship in human society. All three attempt to explain the origins and evolution of kinship and to account for aspects of kinship found universally in human societies. None of these theories, however, belongs to the mainstream of social or cultural anthropology as it is practiced today.

Most modern anthropologists deal with more specific theoretical aspects of kinship. Their interests lie mainly in explaining particular systems or particular aspects of kinship, rather than the origins, evolutionary schemes, and universal aspects of kinship. Their inquiries are both specific, to explain particular systems, and comparative, to explain the range of variation among systems. Murdock's approach to the definition of the family—although it does involve universals—is nevertheless an example of an approach based on a limited but important comparative question (see above *Universality of the family*).

Broadly speaking, current kinship studies consist of three main areas of interest: kinship terminology, descent theory, and alliance theory. Whereas some scholars treat these as distinct and competing approaches, many regard them as complementary.

ENGELS' THEORY

One year after the death of Karl Marx in 1883, Engels, his collaborator, continued the historical materialist approach to the family with a major work called *The Origin of the Family, Private Property and the State*. The book was based heavily on the work of the American lawyer and anthropologist Lewis Henry Morgan—in particular, Morgan's *Ancient Society* (1877), which emphasizes the importance of private property in the development of and changes in family structure.

Origins in primitive communism

According to Engels, the family and human kinship originated from a stage of primitive communism. In this stage, mankind was composed only of hunter-gatherers, people who made their living by foraging and had no agriculture or domesticated animals. Human society consisted of primeval promiscuous "hordes," and people mated indiscriminately with their brothers and sisters. Eventually, kinship came to be reckoned in the female line, because, with such promiscuity, a child did not know who its father was but knew only its mother's identity. Women, according to this theory, held authority over the family.

Groups of men, in Engels' theory, sometimes captured women from other hordes. As mankind advanced, mating between brothers and sisters was forbidden and male warriors were forced to take their brides from adjacent groups. In time, successful groups of males acquired many wives. Patriarchy (authority of the father) replaced matriarchy (authority of the mother) as the condition of human social life. Men might have several wives and concubines who bore children for them, and these children in turn contributed labour for the extended family group.

Monogamy, in Engels' view, came about along with an increase in private property, as men needed a family to which they could pass their inheritance. They could have sexual relations with other women, but they needed to have only one wife in order to make certain that their property would be passed to legitimate heirs. This, according to Engels, explains how the family came into being. The state then grew to enforce the laws of monogamous marriage and the distribution of private property.

Engels' theory hinges on the acceptance of the view that all mankind progressed through the same stages of evolution. In spite of its internal logic, it is accepted only by a small minority of anthropologists today. It was the officially sanctioned theory in the former Soviet Union. Many Western feminists find its explanation of early female authority attractive and convincing. But the majority of scholars believe that it is impossible to describe the origins of the family on the basis of available scientific evidence.

FREUD'S THEORY

Another historically important theory of kinship is that of Freud. He argued that parallels could be drawn between the psychological attitudes of "primitive" adults and those of European children.

The incest taboo

Freud's concern was with the origin of the incest taboo, which is practically universal in human society. He believed that children have a secret desire to commit incest and, in particular, that baby boys experience innate sexual desires toward their mothers. Noting that there is no human society in which such behaviour is sanctioned, he argued that prohibitions against incest were invented in order to combat these tendencies, which would otherwise be socially disruptive. The strictest prohibitions against incest and against marriage with various categories of kin are found, in fact, in what Freud regarded as the most primitive societies. Among Australian Aborigines, for example, a person is permitted to have sexual relations with or take as a spouse only someone from a relatively narrow category of people. Relations with anyone else are regarded as incestuous. In other so-called primitive societies, there are rules governing physical and social contact to such an extent that even behaviour thought of as quite innocent elsewhere, such as looking someone in the eye, is defined as verging on incest. These practices make sense in the context of the social organization of these peoples, but to Freud they were more than this. They illustrated the lengths to which human society must go in order to suppress the incestuous desires he considered natural.

The most speculative aspect of Freud's theory was his position on the origin of the taboos. He concluded that human society must have begun with the invention of rules to stop mating between close kin. Originally there was the primeval horde, which was ruled over by a jealous father. The father had control over and sexual access to all the females of the group, and as his sons grew up he drove them out of the horde. Then, according to Freud's theory, the sons joined together and overcame their father, killing and eating him. As a result of the guilt they felt for committing such a terrible deed, they developed a taboo on the killing of a totem animal, which represented their father. This allowed them to assuage their initial guilt, but the brothers now became rivals of one another, just as before they had been rivals of their father. In order to solve this problem, they invented a second taboo—the taboo on mating within the horde. Henceforth they were required to mate only with members of other hordes.

This idea of the origins of the incest taboo is today taken literally by hardly anyone. Yet it, and similar theories both before and since, have fascinated generations of scholars and led to much research on the question of incest in the marriage rules of different societies.

SOCIOBIOLOGY

Sociobiology originated in the 1970s, becoming established particularly after the publication in 1975 of the American biologist Edward O. Wilson's book *Sociobiology: The New Synthesis*. Sociobiology is an interdisciplinary approach combining biology and the social sciences. Its adherents argue that animal and human behaviour should be studied in conjunction with Darwinian evolutionary theory. They see anthropology as merely a subdiscipline of zoology, and in their view human kinship should be studied in the same way that zoologists study animal behaviour.

The main proponent of sociobiological theory for the study of the family has been the American sociologist Pierre L. van den Berghe. He claimed that human family systems developed as part of a complex interaction between genetic and environmental factors. The genetic factors are not only those that differ between individuals or human groups but also those that are common to mankind generally. Van den Berghe argued that human culture is not merely what is left after everything determined by biology, but rather that culture itself is an outgrowth of natural selection. The widespread occurrence of the nuclear family, the cultural rules of incest avoidance and marriage, and other aspects of kinship are, in van den Berghe's view, products of biologic evolution distinguishing mankind from the apes. Elements of fictive kinship, such as the honorary kin statuses of godparenthood and blood brotherhood, can be seen as attempts by human groups to extend kinship through culture. According to this theory, biologic kinship lies at the root of social behaviour in all human societies.

Influence of biologic evolution on culture

Some scientists have taken this biologic determinist view to yet greater extremes. The American zoologist Robert L. Trivers argued the "nepotism hypothesis." In this theory animals and humans alike are biologically conditioned to sacrifice themselves for the good of other close relatives, so that their own genes may be passed on by these close relatives when they mate. This view can explain the fact that in some societies, such as the Berbers of Morocco, it is considered appropriate and desirable to marry close kin. According to the sociobiological theory, such customs reinforce unconscious desires of self-perpetuation. The reasons given by people in such societies—maintaining close ties with relatives or keeping property in the family—do not, however, generally coincide with the unconscious desires postulated by the sociobiologists, and, for this reason, most anthropologists do not subscribe to sociobiological theory.

KINSHIP TERMINOLOGY

The study of kinship (or relationship) terminology concerns the way people in a society classify their relatives. Many scholars are interested in the social rather than the purely linguistic aspects of these classifications. How is terminology related to membership in descent groups? Which categories of relatives are permitted as marriage partners? Can generalizations be made about the correlation between terminology and social structures? Other scholars, and especially those with a training and interest in linguistics, are more concerned with the formal properties of the terminology itself. Does a given language "merge" parents with parents' same-sex siblings—in other words, call the father and father's brother by the same term? Does it "skew" generations, perhaps by calling every male member of the father's group by the term father? The scholars who address these questions often argue that terminology is independent of social structure, a school of thought that is most common among North American anthropologists.

The significance of terminology. It has long been known that languages classify the world differently. A word in one language does not necessarily have an exact equivalent in another. The way people classify the world reflects the way they think, or, conversely, they think according to the way they classify the world. That the Latin language classifies the father's brother by one term, *patruus*, and the mother's brother by a different one, *avunculus*, reflects the way ancient Roman family life was organized. For English speakers, who use only one term, uncle, for both, the distinction between these two is unimportant; an uncle on the father's side of the family is treated in much the same way as an uncle on the mother's side. The Romans, however, treated them differently, the *patruus* being a stern figure much like the father and the *avunculus* being literally an "avuncular" figure, likened somewhat to a grandfather, who unlike the father was not a figure of authority.

Similarly, the English language distinguishes some categories that other languages do not. English speakers have two terms for the other children of their parents (brother and sister) and another term for the children of their parents' brothers and sisters (cousin). Polynesian languages, on the other hand, have no equivalent of the term cousin; cousins are called by the same terms as brothers and sisters. The fact that speakers of English make this distinction reflects the fact that they treat brothers and sisters differently from cousins, or at least that they regard them as being in a different kind of relationship.

The first person to study the problem of kinship terminology in a scientific manner was Lewis Henry Morgan. Before writing *Ancient Society*, Morgan had discovered that the Iroquois Indians of New York state classify their cousins differently from English-speaking Americans. A male Iroquois calls his sisters and the daughters of his father's brothers and of his mother's sisters all by the terms *ahje* (if they are older than he is) and *kaga* (if they are younger). Yet he calls the daughters of his father's sisters and of his mother's brothers by a different term, *ahgareseh*. He makes similar distinctions between males of his generation, while female Iroquois also employ a comparable, though not identical, classification. The Iroquois traditionally behave toward all these categories of kin according to their classification. For example, an Iroquois can marry a cousin classified as an *ahgareseh*, but not a cousin classified as an *ahje* or *kaga*.

Lewis Henry Morgan and Iroquois terminology

At first Morgan thought the Iroquois were unique, but as he became more familiar with the customs and languages of the North American Indian tribes he realized that this was not the case. Eventually, he sent questionnaires on the subject to all parts of the world, mainly to American consular officials and missionaries. Morgan asked them to fill in the questionnaires with the terms for a wide variety of specific genealogical positions in all the languages the respondents encountered. The results were eventually published under the title *Systems of Consanguinity and Affinity of the Human Family* (1871). This massive work concluded with a discussion of the theory that kinship terminologies reflect preexisting social structure and that one can therefore study the prehistory of society by analyzing known kinship terminologies, an idea that became the basis of Morgan's later book, *Ancient Society*.

Although most anthropologists no longer agree with Morgan's theory, they nevertheless acknowledge the great importance of his discovery of the diversity of kinship terminology structures. Anthropologists now study kinship terminologies, or relationship terminologies (as they are variously known), in relation to existing social institutions, rather than as clues to the past. If a people classify relatives in a particular way, the implication is that they do this for a reason that may be found in their existing social structure. Even where terminologies are conservative and reflect the customs of the past, the categories are nevertheless clues to the perceptions of the people who use them.

Parents' generation terms. In the parents' generation, four forms of classification are found. These are illustrated here with examples of female relatives, though the male equivalents follow the same pattern.

The simplest type, found, for example, in Polynesian societies, classifies all female relatives (or all male relatives) in the parental generation by the same term. A person's mother, mother's sisters, and father's sisters are all called by a term that translates loosely into English as "mother." There is no equivalent to the English term aunt. This type of classification is known as generational terminology.

A more complex type, represented by the English language, distinguishes mother from aunts. This is known as lineal terminology, in reference to its distinction between lineal relatives (those from whom a person is descended, in this case the mother) and collateral relatives (those related through a sister or brother, in this case those classified as aunts or, more precisely, the person's father's and mother's sisters).

A different terminology, the most common in the world's languages, is the bifurcate merging type. This structure makes the distinction between parallel relatives (including lineal relatives and those related through a same-sex sibling link) and cross-relatives (those related through an opposite-sex sibling link). In this system a person's mother and mother's sisters are called by one term and the father's sisters by another. For instance, in Tswana, a Bantu language of southern Africa, a person's mother and mother's sisters are both called *mme* (loosely, but not exactly, translatable into English as "mother"), while the father's sisters are called *rrakgadi*.

Distinguishing parallel relatives from cross-relatives

The ancient Romans used slightly different but related terms for mother (*mater*) and mother's sister (*matertera*), but they sharply distinguished the father's sister (*amita*), who, in their patrilineal society, was closely associated with the kin group of the father. The equivalent terms for male relatives of this generation, as discussed above, were *pater, patruus,* and *avunculus,* the last being derived from *avus,* meaning "grandfather." Although the Latin terminology can be considered bifurcate merging—because relatives on the same side of the family are called by linguistically related, if not identical, terms—strictly speaking the Roman terminology is bifurcate collateral. It "bifurcates" by employing different terms for the father's and mother's sides of the family, but it is "collateral" in that it distinguished lineal relatives from collateral ones by calling the mother's sister, for example, by a different term from the mother. Scandinavian languages, as well as Old English and other Germanic languages, have had kinship terminologies of this type, with no equivalent of the modern English terms aunt and uncle. Instead, relatives are literally called "mother's sister," "father's sister," and so on.

Own generation terms. The classification of terminologies by terms for relatives in a person's own generation (brothers, sisters, and cousins) is more complex. The most prevalent classification is that of George Peter Murdock, who distinguished six types.

Murdock called the simplest type of terminology "Hawaiian." In this type, often found in societies that have a generational-terminology structure for the parental generation, there is no distinction between sisters and cousins; all are termed "sister." Similarly, all the males are called "brother," both by one another and by their "sisters." The term Hawaiian refers to a terminology structure like that found in the Hawaiian language, but it is not peculiar to the Hawaiian language or people. Hawaiian terminologies are also found in other parts of Polynesia and commonly in West Africa.

The "Eskimo" terminology of European societies

The "Eskimo" type is found in English-speaking societies as well as among Eskimo or Inuit groups. The formal definition of an Eskimo terminology is simply that it distinguishes sisters and brothers from cousins. Most European societies have terminologies of this type, as do small-scale hunting and gathering societies such as the !Kung of southern Africa and most (though not all) Eskimo groups in Canada, Greenland, and Alaska. It tends to be found in societies that have cognatic descent systems, that is, those that lack either strong patrilineal or matrilineal principles.

"Iroquois" systems, on the other hand, are generally found in patrilineal and matrilineal societies and in those societies that permit marriage to cross-cousins. This type, which is the most common throughout the world, is structurally related to the bifurcate-merging type. It distinguishes cross-cousins (father's sisters' and mother's brothers' children) from parallel cousins (father's brothers' and mother's sisters' children), and it often classifies parallel cousins by the same terms as brothers and sisters. English-speaking anthropologists have had to invent the words parallel cousin and cross-cousin in order to talk about this distinction, since English speakers do not classify their own kinfolk in this way. Iroquois systems are found commonly among North American Indians, in African societies, in some Asian societies, and in other parts of the world.

Some scholars use the term Dravidian (from the name of the South Asian language family) to describe systems similar to the Iroquois but in which terms for father's sister and mother's brother are identical to those for parents-in-law. The terminologies reflect the fact that a cross-cousin in these societies is considered a person's ideal spouse. The parents of cross-cousins are considered a type of in-law, even if one marries someone else. Terminologies with this feature are found not only in South Asia but also among South American Indians and Australian Aborigines.

Two more complex types are those to which Murdock referred as "Crow" and "Omaha." These are almost invariably found in strongly unilineal societies. As in Iroquois terminologies, cross-cousins are distinguished from parallel cousins, but, in addition, cross-cousins on one or the other side of the family are equated with their parents. Crow terminologies classify the father's sisters' daughters by the same term as the father's sisters (if the society is matrilineal, these people are members of the same matrilineal group). Omaha terminologies classify the mother's brothers' sons by the same term as the mother's brothers (who are all members of the same patrilineal group).

In societies using the Crow and Omaha terminologies, many other relatives are classified by terms that similarly transcend generational distinctions. For example, among the Trobriand Islanders, the term *tabu,* for "father's sister" and "father's sister's daughter," in fact refers to all female members of a person's father's matrilineal group. Male members of the kin group are all termed *tama.* This is sometimes translated loosely as "father," even though it refers not only to a person's actual father but also includes the father's brothers, the father's sisters' sons, and even the father's sisters' daughters' sons.

The Trobriand Islanders

Such systems, found in North America, Melanesia, and Southeast Asia, emphasize lineage membership over generation or genealogical distance. Genealogical distance is a key feature specifically of Eskimo terminologies like the English one, and generation is a key feature of most other forms of kinship terminology. The Crow and Omaha terminologies, however, show that neither genealogy nor generation is universally important for kinship organization.

DESCENT THEORY

Descent theorists are more concerned with groups than with terminology, a theoretical interest that derives from the British tradition of functionalism, which dominated anthropological thinking in Britain and most of the Commonwealth from the 1920s to the 1950s. Functionalists such as A.R. Radcliffe-Brown saw societies as being made up of component parts—institutions (like marriage, chieftainship, or the stock market) and systems (like kinship, politics, or economics). Descent theorists take a functionalist view in their appraisal of the significance of group structure. In descent theory the mechanisms of recruitment to groups, and the social functions such groups perform, are the primary foci of study.

Patrilineal descent. Systems of patrilineal descent are widely distributed. The ancient Greeks and Romans traced descent patrilineally, as do contemporary societies in many parts of Africa, Asia, and the Pacific.

The defining feature of a patrilineal descent system is that membership in a social group is determined by descent through the father. A patrilineal descent group, such as the Greek phratry or the Roman gens, thus includes a person's father, father's father, father's father's father, and so on. In addition, the child of any male member of the group, regardless of the child's own sex, is a member. Thus, a person's father's brothers and sisters (all children of the father's father) are also members of the patrilineal group. Similarly, a man's children are members of his patrilineal group, but a woman's children are not members of hers (the one she was born into); they belong to her husband's group. A woman's own status as a member of her natal group or of her husband's group depends on which such membership the society recognizes.

Matrilineal descent. Matrilineal descent systems are less common than those of patrilineal descent, but they are, nevertheless, found in many widely differing societies in Africa, Asia, and the Pacific, as well as in Amerindian societies. Examples include the Trobriand Islanders of Melanesia, the Crow and Iroquois Indians of North America, the Bemba of Central Africa, and the Nāyars of India. Nāyar society, however, is unusual in that the social role of the father is virtually nonexistent (see above *Universality of the family*). Normally, matrilineal societies maintain family relationships much like those of any other society.

Distinguishing matrilineal descent from matriarchy

Matrilineal descent is defined as descent through the mother. This does not necessarily or even usually imply that a matrilineal group is matriarchal, with authority in the hands of the mother or females, but only that a person traces membership in the group through female links. Authority within the family or kin group may be in the hands of the father or, more commonly, in the hands of the mother's brother. The mother's brother is a focus for the kin group because, for any given person, the mother's brother is the closest senior male in the group. The father is a member of a different matrilineal group.

A matrilineal descent group includes a person's mother, mother's mother, mother's mother's mother, and so on, as well as the descendants of all these people in the female line. In a matrilineal society a person's mother's brothers and sisters, and his own brothers and sisters, are all members of such a group. A woman's children are members of her group, but a man's children are not members of his; they belong to his wife's group.

Double unilineal descent. Double unilineal, or duolineal, descent is very rare. Arguably, a form of double descent exists among groups of Australian Aborigines, but the most definitive examples are found in Africa. The Yakö of Nigeria and the Herero of South West Africa/Namibia and Botswana are the best-known. The principle of double descent is that two kinds of descent group, patrilineal and matrilineal, exist simultaneously in the same society and that each person belongs to both. Often the two groups have different functions. Among the Yakö, for example, residential groupings are patrilineal and land is inherited through the father, while movable property is inherited within matrilineal groups. A person has obligations toward each of the kin groups to which he belongs.

Double descent is similar to, but distinguished from, complementary filiation. Complementary filiation occurs in patrilineal or matrilineal societies when a person has obligations toward kin on the opposite side of the family from which he traces descent. In this case, however, only one kind of descent group is recognized, either patrilineal or matrilineal, not both. The Tallensi of Ghana, for example, are patrilineal, but in this society an individual has obligations not only to his own patrilineal group but also to his mother's patrilineal group.

Cognatic descent. Cognatic, or bilateral, descent is, in a sense, the opposite of double descent. In a cognatic society there are no unilineal groups (*i.e.*, groups descended strictly in the father's or mother's line). A person is reckoned to be equally related to kinfolk on either side of the family. Western societies are mostly cognatic: although surnames, titles of nobility, and so on are inherited patrilineally, there are no longer any patrilineal descent groups as such. For example, a 20th-century Italian, unlike an ancient Roman, feels no closer to his father's brother's child than to any other cousin. They share the same surname, but they do not share membership in a descent group comparable to the Roman gens.

Cognatic descent and the modern world

Most modern industrialized nations have cognatic kinship systems, and so, too, do most hunting and gathering societies. In the latter case, persons may join either their father's or mother's band or, often, the band of the spouse or some more distant relative. These bands, consisting of perhaps 25 people among most African and Asian hunter-gatherers, or up to a few hundred in the case of native North Americans, are descent groups, even though they are not unilineal descent groups.

Finally, there are some societies that recognize an ideal of patrilineal descent but in which persons may opt for tracing descent through a female link. This arrangement, known as ambilineal descent (through either line) bears some relation to the cognatic descent system of egalitarian hunter-gatherers, but it is found instead in the hierarchical societies of Polynesia. In these societies, a person may join the group that offers the most prestige, either the father's or the mother's, but in so doing the person gives up any rights held in relation to the other group.

Fictive kinship. *Forms of fictive kinship.* Perhaps the best-known form of fictive kinship is godparenthood. This is an institution found in many Christian societies, where the ritual sponsors of a child at baptism, its godparents, act as quasi-parents, promising to look after the spiritual interests of the child. The relationship between godparent and godchild is not, strictly speaking, one of kinship. Although godparents are regarded as being like parents in certain ways, they are not seen as part of the actual kinship system. Nevertheless, certain elements of the godparent relationship come very close to kinship. For example, marriage to a godchild or to a godparent's child may be forbidden. Such rules mimic those of the incest taboo and of close kin exogamy (obligatory marriage outside the group).

In addition to the relationship between godparent and godchild, relations are established between the godparents and parents. This is particularly true in certain Roman Catholic societies, notably in western Mediterranean and Latin-American countries. There, the notion of compadrazgo (as it is called in Spanish) includes fully this cluster of relationships; parents and godparents are said to be compadres, and they are required by custom to help each other in times of hardship, to lend each other money, and to offer support, for example, at festival times.

Fostering may also be regarded as a form of fictive kinship in which foster parents provide for children and give moral as well as material support. Fostering differs from adoption in that the latter incorporates the child into the family fully and thus provides for true (social) kinship rather than merely fictive kinship. The distinction is not absolute, however, because specific ideas about what is and what is not kinship differ between cultures.

Blood brotherhood

Fictive kinship also includes blood brotherhood and other institutions in which people maintain a special, but not quite a kin, relation to one another. Among various African peoples, for example, bonds of blood brotherhood unite individuals in formal ties that are invoked in times of need. The Azande of Central Africa initiate such ties by a ritual in which each party swallows some of the other's blood. Other African peoples initiate the bond by mixing blood directly in wounds cut for the purpose. Such relationships sometimes unite not only individuals but also groups, as for instance among the Chaga of Tanzania, where blood brotherhood ties between chiefs establish alliances between their entire chiefdoms.

The distinction between real and fictive kinship is not precise but depends on many cultural factors. The only thing all fictive kinship has in common is that some aspect of the relationship is regarded as fictive, while another aspect is regarded as true kinship.

The metaphorical use of kinship terms. In all languages kinship terms form a recognized vocabulary used to designate relatives (see above *Kinship terminology*). Yet these terms are not always used only in their literal, kinship context. They may be employed in fictive kinship contexts, as in blood brotherhood or godparenthood, or yet more metaphorically in other contexts. In politics reference is sometimes made to "Big Brother," to "brothers and sisters" in the black power movement, or to "sisters" in the feminist movement. In a religious context there are "fathers" in the priesthood and "mother superiors," "sisters," and "brothers" within religious orders. Children may address their parents' friends as, for example, "Aunt Mary" or "Uncle Bill."

In anthropological jargon these usages are said to be ones of connotation rather than signification, since they identify attitudes and behaviour and not kin relationship proper. In contrast, the *!*Kung classify everyone who bears the same name as close kinsmen as if they were relatives proper. If a *!*Kung man's sister is called Kxaru (a female name), then all women named Kxaru are his "sisters." A *!*Kung man may not sit too close to his sisters or tell sexual jokes in their presence, and of course he cannot marry them. The same rules apply to his sisters' namesakes. Such customs go further than those of "sisters" in the feminist movement, for example, because they identify "true" and not merely metaphorical kinship—at least as the *!*Kung see it. The *!*Kung believe that all namesakes are descended from the same original namesake ancestor, and in effect they treat the status of namesake as a genealogical position, like father, mother, brother, sister, son, or daughter.

Residence patterns. In some societies there are patterns of residence created and maintained by explicit rules. For example, in many hunting and gathering societies a newly married couple must reside for a time in the home of the wife's parents so that the young husband can hunt and provide game meat for them. He must prove himself a good provider before he is permitted to take his wife to his own family's place of residence or to establish a residence among a different band in his tribal territory. In many other societies the rules are not so explicit or obligatory, but it may still be regarded as appropriate for a couple to live in one place rather than another.

Residence patterns and descent groups

Three commonly found patterns of postmarital residence bear a direct relation to rules of descent. These are virilocal residence (coupled with patrilineal descent), uxorilocal residence (coupled with matrilineal descent), and avunculocal residence (also coupled with matrilineal descent).

Virilocal residence literally means residence in the locality of the husband. Sometime this is called patrilocal residence (residence with the father) because the husband's place of residence is also normally that of his father, or simply because the children of the marriage will grow up in their father's natal home. The consistent practice of virilocal residence automatically creates groupings of patrilineally related kin, each residing at the same locality. This may be a large clan territory, but more commonly it is a smaller place. Virilocal residence may be permanent or temporary. If only temporary, it may have less effect on the maintenance of patrilineal kin groups. In fact, the practice of virilocal residence is common in matrilineal and cognatic societies as well as in patrilineal ones, but, in cases where descent is not congruent with residence, it does not affect descent group organization.

Uxorilocal residence is residence in the wife's place. It is also known as matrilocal residence (residence with the mother). Just as virilocal residence keeps men of a patrilineal group together and disperses the women, so uxorilocal residence keeps matrilineally related women together and disperses the men. In some societies—for example, the Bemba of Zambia—uxorilocal residence permits a daughter to work the fields she will inherit from her mother.

An alternative residence pattern, frequently found in matrilineal societies but only rarely, if ever, found elsewhere, is avunculocal residence. The term means residence with a man's mother's brother (Latin *avunculus*). Among the Trobriand Islanders (the best-known example of this residence rule) each boy leaves his parents' marital home well before the age of marriage in order to live in the village of his mother's brother. Although he has not lived there before, he is taught to regard the village as his own because it is the village of his matrilineal kin group. His brothers, his mother's sisters' sons, and other members of his matrilineal kin group also move there when they reach the appropriate age. Girls remain in their natal village until marriage, when they move to the villages of their respective husbands. These villages, of course, are those of their husbands' mothers' brothers, rather than those in which their husbands were brought up. This practice creates residential units consisting of matrilineally related males, their wives (who come from other kin groups), and their young children. The women through whom all the men are related are forever dispersed, living first in the villages of their fathers, then in the villages of their husbands, but never in their "own" villages. Such an arrangement works well in a society such as Trobriand, in which descent is through women but authority is in the hands of men.

A fourth possibility would be a form of organization in which the female members of a patrilineal group reside together and the male members of the group are dispersed. This pattern would be generated by a rule of amitilocal residence (from *amita,* Latin for "father's sister"), which would require females to live with their father's sisters and males to move in with their wives. However, this possibility, the mirror image of avunculocal residence, is unattested in the ethnographic record.

Various other possibilities are found. These patterns do not create or maintain unilineal kin-based residential groups as do the types discussed above, but they can have an effect on building cognatic kinship groups or, indeed, in dispersing unilineal groups. The kind of residence variously known as natolocal (residence in the place where one was born) or duolocal (residence in two places) requires that each married partner remain in separate childhood homes rather than form a new home together after marriage. Although rare, it does occur in some West African societies, if only as an initial stage in married life. A somewhat similar pattern involves men living in a "men's house," with only women and children living in the family home. This kind of residence, which has no Latin-derived term to describe it, is not uncommon in Papua New Guinea and elsewhere in Melanesia.

Neolocal residence and the modern world

A much more common type of postmarital residence is neolocal, which involves moving to a new place of residence, neither the wife's nor the husband's natal home. Ambilocal residence, in contrast, is residence either in the wife's home or in the husband's, often when a couple need the material support of one set of parents before setting up a home of their own. Both neolocal and ambilocal residence are found as alternatives in most modern Western societies, but neolocal residence is generally the norm. Neolocal residence is particularly common, worldwide, in those societies in which the typical household is made up of a single nuclear, or conjugal, family.

Finally, uxori-virilocal and other combinations of the basic residence patterns create greater complexity in the fitting of residence with the cycle of family life. In uxori-virilocal residence the couple live first with the wife's group and later with the husband's. The example of a hunting and gathering society in which a husband must live for a time in his wife's group and hunt on behalf of his in-laws is discussed above. If after this period of "bride service" he and his wife go to live in his own home territory, the family cycle may be described as involving uxori-virilocal residence.

It is important to remember that the labels used in this discussion describe only the typical rules or practices of postmarital residence, and especially the ideal type in any particular society. There is great variety among the world's societies, and within each society, in residential groupings and family structures. These patterns depend not only on the ideal rule of residence but also on the size of the household, whether polygamy is permitted, the size and arrangement of the community, and many other cultural, demographic, and spatial factors.

ALLIANCE THEORY

Alliance theory emphasizes the marital bond and relations between groups. It is derived from French structuralism, in particular from the work in the field of kinship by Claude Lévi-Strauss and Louis Dumont. Structuralism is more concerned with the collective thought of a people than with their social institutions.

The English term alliance, in its technical sense, carries the specific meaning of alliance through marriage, a connotation derived directly from the French word *alliance* (meaning "marriage"). Alliance theorists pay close attention to those kinship systems in which rules of marriage between groups appear to dominate a large area of social endeavour. In particular, they analyze the rules that determine which people a person may marry and which people he may not. These rules, in turn, are based on rules of incest avoidance.

The incest taboo. All societies have a concept of incest, and all societies have a prohibition, or taboo, against it. Definitions of incest vary according to definitions of who is close kin. Reactions to violations of the taboo also vary from society to society. In some cases incest is thought of with abhorrence; in other cases, with mild amusement. The vehemence of its condemnation may also depend on which specific incestuous relationship is involved, whether the parties are children or adults, and the circumstances of the violation.

No one knows how the incest taboo originated. Theories of its origin are diverse. As discussed previously (see above *Freud's theory*), Sigmund Freud believed that people have an innate desire to commit incest and that the incest taboo prevents them from carrying out such deep-seated desires. In contrast, the Finnish anthropologist Edward Westermarck, writing some two decades before Freud, argued that human beings find naturally abhorrent the idea of sex with close family members. His theory was that "familiarity breeds contempt"; in other words, the innate desire is to avoid incest, not to commit it.

Incest taboos and exogamy

Closely tied with the incest taboo is the practice of exogamy, or marriage outside the group. However, while these matters are clearly related, there are crucial differences. First, by definition, incest involves sex and exogamy involves marriage. Second, incest taboos and rules of exogamy do not always coincide. In other words, in some societies it is not considered incestuous to have sexual intercourse with persons who are forbidden as spouses. Third, incest taboos are purely proscriptive, whereas rules of exogamy may be prescriptive as well. That is, the former rules define what is not permitted, while the latter may determine whom one ought to marry. Indeed, in many societies the rules of exogamy are stated in a strongly positive way, notably in those societies in which the social structure is closely bound up with rules of marriage to particular cousins.

Elementary and complex kinship structures. According to Lévi-Strauss, the incest taboo and exogamy lie at the root of human society. The incest taboo is on the one hand natural and universal, since every society recognizes it, and on the other hand cultural, since exactly which relatives are forbidden to marry vary widely among societies. Generally speaking, the specification of the taboo and the consequent marriage rules take two possible forms; Lévi-Strauss called these "elementary" and "complex."

Elementary kinship structures are those in which there exists a positive rule for marriage to someone of a particular kinship category, for example, to a cross-cousin (father's sisters' and mother's brothers' children) or someone of a wider category including cross-cousins. In principle, elementary structures offer limited choice of a spouse. Complex kinship structures (which, ironically, are much simpler to understand) are those that have negative marriage rules—*i.e.*, those specifying which persons one may not marry. Since ancient times all Western societies have had complex structures, because under their rules of kinship, brothers, sisters, children, and other close relatives may not marry, although a person may marry anyone else.

Modern societies in most parts of the world have complex structures—those in which the patterns of marriage are not precise or easily discernible and, hence, are "complex." Many scholars believe that these complex systems emerged from elementary ones. Certain systems fall between the elementary–complex distinction. The traditional kinship systems of some native North American and West African peoples (the so-called Crow-Omaha systems), for example, have a complex set of negative marriage rules, but they have so many such rules that the choice of a spouse is as restricted as in an elementary system. In such societies entire clans, and even clusters of clans presumed to be related, are forbidden as possible spouses.

Prescriptive and nonprescriptive systems

Since the formulation of Lévi-Strauss's theory in the 1940s, anthropologists have tried to define more precisely the essential properties of elementary structures. For the British anthropologist Rodney Needham the crucial distinction is not between elementary and complex but between prescriptive and nonprescriptive (formerly called preferential) systems. Prescriptive systems include those in which the kinship terminology defines exactly all the marriage possibilities. In some such societies the term for wife and cross-cousin is the same, whether a man actually marries one of his cross-cousins or not. The implication is simply that a man must marry someone of the category that includes cross-cousins. For a person born into a society with a prescriptive terminology, marriage to a cross-cousin is a logical consequence of the terminology structure itself.

The marriage of cousins. Elementary structures are of two types. The first type involves direct or restricted exchange, which allows the exchange of sisters as wives between groups. This system is a consequence of a rule requiring marriage to cross-cousins and more distant relatives on either side of the family who are addressed with the same term as cross-cousins. The second type involves generalized exchange, which permits a man to marry only a woman related through his mother. The closest relative he can marry is his mother's brother's daughter. A woman marries her father's sister's son or some more distant relative called by the same term as the father's sister's son. A third form of elementary structure, delayed direct exchange (involving a repeated pattern of father's sister's daughter/mother's brother's son marriages), was postulated by Lévi-Strauss, but it does not exist except as a theoretical possibility.

Systems of direct exchange are often described as "symmetrical," as cross-cousins on both sides of the family are called by the same term, and in principle a person may marry anyone of the cross-cousin category, irrespective of the side of the family or genealogical distance. Direct exchange in its most literal sense is the exchange of women as wives between groups. Many peoples with perfectly symmetrical kinship terminologies do not actually practice this pattern of exchange, however. Symmetrical systems occur in the Indian subcontinent, among most native South American peoples, and among the Australian Aborigines. The Aborigines, in particular, have extremely elaborate cosmological structures with which they classify virtually every aspect of the known universe; these structures match their kinship terminologies and rules of marriage with mathematical precision.

Systems of generalized exchange are said to be "asymmetrical," as the kinship terms for cousins on each side are different, and a man may marry only on his mother's side and a woman only on her father's. In theory, such systems widen the circle of social relationships. The men of Group A marry the women (their mothers' brothers' daughters) of Group B; but the women of Group A may not marry the men of Group B, since that would imply direct exchange or a symmetrical relationship. They must marry the men of Group C or D or E, and so on. Because of the asymmetrical nature of the relationships between such groups, generalized exchange tends to create, or at least sustain, hierarchical relations. In some societies (particularly those practicing Hinduism), it is believed that the husband's group is superior to the wife's. Thus, virtually by definition, a man's in-laws are his inferiors and a woman's are her superiors. In other cases, including many tribal societies in contemporary Burma and Indonesia, the reverse is true: a woman's group is regarded as superior, and a man's in-laws are of higher status than he is. Among certain Indonesian peoples, however, intermarrying groups are linked in a complete circle of marital alliances. Closing the circle prevents any one group from obtaining outright superiority over the others, since each group owes deference to the group from which its wives come.

BIBLIOGRAPHY. MICHAEL ANDERSON, *Approaches to the History of the Western Family, 1500–1914* (1980), discusses the main approaches and includes a useful bibliography. Important historical collections of essays are PETER LASLETT (ed.), *Household and Family in Past Time* (1972), based essentially on the demographic approach; and JACK GOODY, JOAN THIRSK, and E.P. THOMPSON (eds.), *Family and Inheritance: Rural Society in Western Europe, 1200–1800* (1976), illustrating the household economics approach. Current research in the field is published in the *Journal of Family History* (quarterly). For discussions of family and kinship in ancient Greece, see S.C. HUMPHRIES, *Anthropology and the Greeks* (1978, reprinted 1983); and W.K. LACEY, *The Family in Classical Greece* (1968, reprinted 1984). On ancient Rome, see BERIL RAWSON (ed.), *The Family in Ancient Rome: New Perspectives* (1986); and PHILIPPE ARIÈS and GEORGE DUBY (eds.), *A History of Private Life: From Pagan Rome to Byzantium* (1987; originally published in French, 1985), the first volume of a projected series that will provide coverage up to the second half of the 20th century. For the medieval period and after, see JACK GOODY, *The Development of the Family and Marriage in Europe* (1983); CHRISTIANE KLAPISCH-ZUBER, *Women, Family, and Ritual in Renaissance Italy*, trans. from French (1985); and DAVID HERLIHY and CHRISTIANE KLAPISCH-ZUBER, *Tuscans and Their Families: A Study of the Florentine Catasto of 1427* (1985; originally published in French, 1978). The most detailed study of the family from 1500 is LAWRENCE STONE, *The Family, Sex and Marriage in England, 1500–1800* (1977). Another general study, with emphasis on France, is JEAN-LOUIS FLANDRIN, *Families in Former Times: Kinship, Household, and Sexuality* (1979; originally published in French, 1976). MICHAEL ANDERSON, *Family Structure in Nineteenth Century Lancashire* (1971), is a major case study. SYBIL WOLFRAM, *In-Laws and Outlaws: Kinship and Marriage in England* (1987), examines more recent family history, especially from a legal point of view. For a philosophical treatment of the subject, see EMMANUEL TODD, *The Explanation of Ideology: Family Structures and Social Systems* (1985; originally published in French, 1983).

Essay collections on the modern family include NORMAN W. BELL and EZRA F. VOGEL (eds.), *A Modern Introduction to the Family*, rev. ed. (1968); MICHAEL ANDERSON (ed.), *Sociology of the Family*, 2nd ed. (1980); ROSE LAUB COSER, *The Family, Its Structure & Functions*, 2nd ed. (1974); C.C. HARRIS *et al.* (eds.), *The Sociology of the Family* (1979); and ROBERT M. NETTING,

RICHARD R. WILK, and ERIC J. ARNOULD (eds.), *Households: Comparative and Historical Studies of the Domestic Group* (1984). The leading journals in the field are the *Journal of Marriage and the Family* (quarterly); and *Family Relations* (quarterly), the latter devoted almost exclusively to applied studies. A detailed introduction to the sociological study of the family is F. IVAN NYE and FELIX M. BERARDO, *The Family: Its Structures and Interaction* (1973), dealing extensively with the family cycle and marriage. See also F. IVAN NYE (ed.), *Family Relationships: Rewards and Costs* (1982); and STEVEN L. NOCK, *Sociology of the Family* (1987). C.C. HARRIS, *The Family and Industrial Society* (1983), analyzes the modern family within the larger society; and D.H.J. MORGAN, *Social Theory and the Family* (1975), gives a more theoretical account. WADE C. MACKEY, *Fathering Behaviors: The Dynamics of the Man-Child Bond* (1985), is a cross-cultural study. BERT N. ADAMS, *The American Family: A Sociological Interpretation* (1971), now slightly dated, describes the subject from a sociological point of view; while DAVID M. SCHNEIDER, *American Kinship: A Cultural Account*, 2nd ed. (1980), gives an anthropological perspective. ANTHONY CLARE, *Lovelaw: Love, Sex & Marriage Around the World* (1986), based on a British television series, presents a comparative view.

A useful collection of articles on socialization in a variety of cultures is JOHN MIDDLETON (ed.), *From Child to Adult: Studies in the Anthropology of Education* (1970, reprinted 1977). JOSEPH M. HAWES and N. RAY HINER (eds.), *American Childhood: A Research Guide and Historical Handbook* (1985), is a detailed history. Modern problems are discussed in SHEILA B. KAMERMAN and CHERYL D. HAYES (eds.), *Families That Work: Children in a Changing World* (1982). A negative view of the modern family is presented in DAVID COOPER, *The Death of the Family* (1971); and R.D. LAING, *The Politics of the Family and Other Essays* (1971). PHILIP ABBOTT, *The Family on Trial: Special Relationships in Modern Political Thought* (1981), surveys the opinions of philosophers and social theorists. MICHAEL YOUNG and PETER WILLMOTT, *Family and Kinship in East London* (1957, reprinted 1986), and *The Symmetrical Family: A Study of Work and Leisure in the London Region* (1973, reprinted 1984), are important studies. Another classic study is CONRAD M. ARENSBERG and SOLON T. KIMBALL, *Family and Community in Ireland*, 2nd ed. (1968). Feminist perspectives are presented in ANN OAKLEY, *Housewife* (1974; U.S. title, *Woman's Work: The Housewife, Past and Present*, 1975); and JESSIE BERNARD, *The Future of Marriage*, 2nd ed. (1982). ROBERT S. WEISS, *Marital Separation* (1975), is based on a study made in the United States. PAUL BOHANNAN (ed.), *Divorce and After* (1970), is a collection of studies of divorce in several countries. ESTHER WALD, *The Remarried Family: Challenge and Promise* (1981), describes the topic from a family therapist's point of view. Adoption, divorce, and other aspects of family life are discussed in SHEILA B. KAMERMAN and ALFRED J. KAHN (eds.), *Family Policy: Government and Families in Fourteen Countries* (1978). Forms of family organization are studied in WILLIAM J. GOODE, *The Family*, 2nd ed. (1982). See also KINGSLEY DAVIS (ed.), *Contemporary Marriage: Comparative Perspectives on a Changing Institution* (1985). An overview of African family studies is presented in DIANE KAYONGO-MALE and PHILISTA ONYANGO, *The Sociology of the African Family* (1984). The effects of labour migration of Southern African families are discussed in COLIN MURRAY, *Families Divided* (1981). A very different geographical area is studied in RUBIE S. WATSON, *Inequality Among Brothers: Class and Kinship in South China* (1985).

The theory of the universality of the family is set forth in GEORGE PETER MURDOCK, *Social Structure* (1949, reprinted 1965). C.J. FULLER, *The Nayars Today* (1976), deals with the Nayar debate. A good discussion of the matrifocal family is R.T. SMITH, "The Matrifocal Family" in JACK GOODY (ed.), *The Character of Kinship* (1973), and other essays in this collection are also valuable. Specific problems of an Israeli kibbutz are discussed in MELFORD E. SPIRO, *Children of the Kibbutz*, rev. ed. (1975); and YONINA TALMON, *Family and Community in the Kibbutz* (1972).

Essay collections on kinship, with both comparative and descriptive studies, include PAUL BOHANNAN and JOHN MIDDLETON (eds.), *Kinship and Social Organization* (1968); JACK GOODY (ed.), *Kinship* (1971); NELSON GRABURN (ed.), *Readings in Kinship and Social Structure* (1971); DAVID M. SCHNEIDER and KATHLEEN GOUGH (eds.), *Matrilineal Kinship* (1961, reprinted 1974); and A.R. RADCLIFFE-BROWN and DARYLL FORDE (eds.), *African Systems of Kinship and Marriage* (1950). RODNEY NEEDHAM (ed.), *Rethinking Kinship and Marriage* (1971), contains a number of important papers, particularly from the perspective of alliance theory. Among introductory texts are ROBIN FOX, *Kinship and Marriage* (1967, reprinted 1983), especially good on alliance theory, though feminist critics have raised objections to its treatment of society as male-dominated; ROGER M. KEESING, *Kin Groups and Social Structure* (1975), valuable for analysis of descent and residential arrangements, though many scholars disagree with specific aspects of its portrayal of alliance structures and kinship terminologies; and LOUIS DUMONT, *Introduction à deux théories d'anthropologie sociale* (1971), an excellent treatment of both descent and alliance and of the main differences between British and French approaches to the study of kinship. Theoretical and methodological issues in the study of kinship are more fully discussed in ALAN BARNARD and ANTHONY GOOD, *Research Practices in the Study of Kinship* (1984). Another important theoretical account of the subject is DAVID M. SCHNEIDER, *A Critique of the Study of Kinship* (1984).

Most anthropological studies of kinship in particular societies are published in specialist journals or as chapters in anthropological monographs. Among book-length studies dealing mainly with kinship are JONATHAN P. PARRY, *Caste and Kinship in Kangra* (1979), on North India; BRONISLAW MALINOWSKI, *The Sexual Life of Savages in North-Western Melanesia*, 2 vol. (1929, reprinted in 1 vol., 1987), a classic study of the Trobriand Islanders; HILDRED GEERTZ and CLIFFORD GEERTZ, *Kinship in Bali* (1975); E.E. EVANS-PRITCHARD, *Kinship and Marriage Among the Nuer* (1951, reprinted 1973), on the Nuer of the southern Sudan in Africa; I. SCHAPERA, *Married Life in an African Tribe* (1940, reissued 1966), on the Tswana of Botswana; ADAM KUPER, *Wives for Cattle: Bridewealth and Marriage in Southern Africa* (1982); FRED EGGAN, *Social Organization of the Western Pueblos* (1950, reprinted 1973), on the Indians of the American Southwest; RAYMOND FIRTH, JANE HUBERT, and ANTHONY FORGE, *Families and Their Relatives: Kinship in a Middle-Class Sector of London* (1969); and KENNETH MADDOCK, *The Australian Aborigines: Portrait of Their Society*, 2nd ed. (1982). Essays illustrating the flexibility of the concept of kinship over time and place are collected in LINDA S. CORDELL and STEPHEN BECKERMAN (eds.), *The Versatility of Kinship* (1980).

FRIEDRICH ENGELS, *The Origin of the Family, Private Property, and the State* (1902, reissued 1985; originally published in German, 1884); and SIGMUND FREUD, *Totem and Taboo* (1918, reissued 1983; originally published in German, 1913), contain their respective theories. The sociobiological view, with important statements on the relation between animal and human family behaviour, is presented in PIERRE L. VAN DEN BERGHE, *Human Family Systems: An Evolutionary View* (1979, reprinted 1983); and ROBIN FOX (ed.), *Biosocial Anthropology* (1975). EDWARD WESTERMARCK, *The History of Human Marriage*, 5th ed., 3 vol. (1921, reprinted 1971), includes his theory of incest. A later discussion of the subject is found in JAMES B. TWITCHELL, *Forbidden Partners: The Incest Taboo in Modern Culture* (1987). On alliance theory and elementary structures, see CLAUDE LÉVI-STRAUSS, *The Elementary Structures of Kinship*, rev. ed. (1969, originally published in French, 1949), and his "Future of Kinship Studies," *Proceedings of the Royal Anthropological Institute of Great Britain and Ireland* (1965), pp. 13–22; as well as RODNEY NEEDHAM, "Prescription" and "Alliance," *Oceania*, respectively, in 43:166–181 (March 1973) and 56:165–180 (March 1986). For an analysis of the South Indian symmetrical system from this perspective, see ANTHONY GOOD, "Prescription, Preference and Practice: Marriage Patterns Among the Kondaiyankottai Maravar of South India," *Man*, 16(1):108–129 (March 1981).

(A.J.B.)

Family Law

In the past, family law has been closely connected with the law of property and succession, and from the records available, it must have had its principal origins in the economic and property questions created by the transfer of a woman from her father's family to the power and guardianship of her husband. Even in regard to parent and child, such legal concepts as guardianship, custody, and legitimacy were associated with family power structures and family economic interests. Family law also has to do with matters of personal status—for example, the question whether X is to be considered married or single or whether Y is to be classed as legitimate—although the incidents and importance of these distinctions often lead back to the law of property.

Family law shares an interest in certain social issues with other areas of law (*e.g.,* criminal law). One of the issues that has received a substantially increased amount of attention, from various points of view, is the very difficult problem of violence within the family. This may take the form of physical violence by one adult member on another (in this case the woman is almost always the victim), or by an adult on a child, or of some other form of violent or abusive conduct within a family circle. Difficulties can arise when the wrongdoer returns to cohabitation with the person who has made a complaint. In serious cases the only real solution may be a termination of cohabitation, or the removal of an abused child from the family unit, for example, into some form of public or foster custody. The problem is one of social importance, and some studies (*e.g.,* several done in North America) indicate that a high proportion of violent crime originates in family units.

This article is not a treatise on the family laws of the world (which would require at least a volume) but a consideration of the role of law in regard to the family and an effort to identify the main problems on a comparative basis. In recent decades, family law has been subject to reexamination in many parts of the world, and the greater legal status and independence acquired by married women has been a catalyst.

This article is divided into the following sections:

FAMILY GROUPS

A family group has a certain internal structure as well as relationships between itself and third parties. Family groups in some societies have tended to be complex, as, for example, the Roman paterfamilial group, the Chinese upper-class family, the Indian joint family, the samurai family in Japan, and many customary family structures in Africa. The family may be a part of a larger group such as the tribe or clan.

The two-parent family. At present the dominant form of the family group consists of two spouses and the children they have produced or adopted. The law, therefore, is concerned mainly with the rights and duties of husband and wife and parent and child. In a strictly monogamous society the law will forbid a husband to be married to more than one woman at the same time, while in other societies it will regulate the number of wives (as does Islāmic law). Some two-parent families are, in effect, matriarchal because the adult male is so frequently absent, as in fishing communities or among peoples with high concubinage rates. In a number of countries (although in different degrees) there is a growing acceptance of unmarried cohabitation, and there is increased concern about the legal implications of such cohabitation. Legal status

Traditionally, family law has not concerned itself much with unions that are not commenced by legal marriage, though some systems of law permit the recognition of a "natural" child by a father for such purposes as inheritance or support. The family group based on concubinage has been largely neglected by the law because such unions are often transitory and difficult to define, are considered immoral, occur mainly among poorer or less educated classes (as in some parts of Latin America), or are associated with an inferior status of the female (particularly in Asian and African countries).

The one-parent family. Where divorce and separation are common and where welfare programs are available to assist dependents, the one-parent family acquires an importance that is not adequately reflected in traditional law. It may be necessary to adapt the law to a greater extent to the needs of one-parent families in such areas as the organization of family and child welfare services and the legal and administrative machinery for family support, employment assistance, day nurseries, and the like. The head of a single-parent household may have difficulty affording the high cost of child care while working or training, especially on a modest or low income.

Even where the family is a two-parent group, it may encounter some of the problems of the one-parent family if the woman is employed outside the home. Some European countries, and the People's Republic of China, have probably gone further than most in proportions of women in employment, but many other countries also have changing patterns of female employment. In the poorer classes generally, women have traditionally worked outside the home at unskilled jobs; a newer development is the growing number of middle-class married women who are employed full-time or part-time for personal satisfaction, increased standard of living, or both.

Legal consequences of marriage. Two persons might produce the economic incidents of marriage by executing appropriate contracts or settlements. On this argument, a marriage provides a technically simple way of achieving things the parties could do for themselves in finance and property matters with greater expense and complexity. In some legal systems, in which agreement on property arrangements is central to the status of a legal wife, a contract in conventional form is the core of the constitution of marriage. The contract may be complex, with a variety of clauses, as in Muslim law or (more so formerly) as in major family unions under French or English law. In most countries today, however, the legal documentation of a marriage is mainly a registration of the event. So basically, in the legal sense, a marriage is the implied creation of certain rights or obligations such as maintenance, marital property and succession rights, and the custody of minor children.

In modern systems, the parties to a marriage can usually create the economic incidents of the marriage by a separate agreement. In some early legal systems and in present systems in which customary family law pertains, there is little choice as to the economic incidents of marriage because these are fixed by custom. In legal systems that allow substantial scope for personal independence, the spouses can take up a position of their own as to the economic basis of their family group by means of a marriage contract or a will.

Status and contract

According to the English legal scholar Sir Henry Maine, legal history shows a movement from "status" to "contract"—meaning that modern private law is less concerned with a person's class (*e.g.*, slave, illegitimate son, serf, freeman, Roman citizen) than it is with voluntary agreements among persons. A maintenance obligation has a different practical significance in a country such as Sweden, where most married women are employed and there are extensive welfare programs, than, for example, in India. Rights of intestate succession have a different social impact in a country where most people make wills than in one where most die intestate. In many countries there has been a tendency in the law to allow increasing freedom in setting up the family group and establishing its economic base. This is not true of some countries, and generally Communist legal systems impose at least a matrix of mandatory general principles designed to promote the political and social philosophy of the state. The extent of mandatory regulation, as compared with leaving decisions to the spouses voluntarily, is one of the important issues facing family law at the present time.

One feature that distinguishes marriage from a simple contract is that, in many countries, the parties cannot release themselves by mutual agreement. But some legislation in North America and western Europe comes close to permitting this; the grounds of divorce have been so widened that the marriage can be terminated, for example, after a period of separation.

The social environment. The family group is in some respects a microcosm of society, reflecting within it many facets of the whole social and legal environment. The great religions of the world have taken a special interest in family law, seeing in it opportunities for extending their moral and spiritual influence. Family law has at times been an element in promoting the interests of a particular class; in many countries there have been social hierarchies sustained by marriage and property laws. Practicing lawyers and the courts devoted much of their time to the interests of the dominant class. The family structures of the poor and the peasantry received much less attention in the law; the family law of these classes had more to do with workhouses, charitable institutions, unemployment relief, and welfare services. The 20th-century revolutions in Russia and China had as a main target the family structures of existing quasi-feudal regimes and consequently made large-scale changes in family law. The introduction of the Meiji code in Japan in 1898 similarly involved basic changes in the traditional family law, marking the emergence of a new society.

The wide differences in social organization and custom indicate that there can be no universal "best" pattern for family law. The legal regulation of familial relationships should be approached with caution lest the prejudices of a majority be imposed unnecessarily on the private lives of individuals. As the English philosopher John Stuart Mill wrote in his "Essay on Liberty," "There is a limit to the legitimate interference of collective opinion with individual independence; and to find that limit, and maintain it against encroachment, is as indispensable to a good condition of human affairs, as protection against political despotism."

The range of problems falling within the general scope of family law may conceivably increase in the future, and there are legal scholars who predict that, within the next 50 or 100 years, family law may experience some of the most critical events in the history of human societies. First, rising population in some parts of the world may bring profound changes in laws relating to the family. Methods of limiting population and of controlling reproduction and heredity will, to the extent they are put into practice, have an important effect on family relationships and the principles of family law. Second, an increasing life expectancy is itself an important influence on marriage and family structure, because it lengthens the average cohabitation until dissolution of a marriage by death. Third, new dimensions in relations between the sexes could be introduced by a developed biotechnology in the control and management of genes, cells, etc., undoubtedly raising new legal problems. Fourth, the accelerating tendency for people to group in huge urban complexes is a social force bearing on the traditional structures of family law.

CHILDREN

Laws relating to the care of children

It is almost universally the rule that natural or adopting parents have a primary duty to maintain their minor children. In the great majority of cases, the care and upbringing of a child belongs to its biological parents automatically, without regard to their qualification or suitability. No doubt this arrangement was due originally to its convenience and to lack of alternatives, although examples may be found of groups rearing their children in common (usually in tribal societies). The parental system has been justified on religious grounds. Thus, in an Irish case the court declared: "The authority of a father to guide and govern the education of his child is a very sacred thing, bestowed by the Almighty, and to be sustained to the uttermost by human law." At least one criticism of this system is the inequality of opportunity and upbringing it can offer one child as compared with another.

Common-law view of illegitimacy

Legitimacy. By the common law of England, an illegitimate child was a *filius nullius* (without relatives). There may have been two main reasons for this former, discriminatory attitude. First, certain unions between the sexes were designated as lawful marriages, and a man of importance, agreeing to his daughter's marriage, would insist on her having the status of legal wife. Second, paternity, in the legal sense, was easier to establish in the case of a lawful marriage than in the absence of a marriage. The common law of England, for example, presumes in favour of legitimacy when the child is born in lawful wedlock, even if the biological facts may be otherwise. Civil-law systems—those derived from Roman law—have been less absolute than the common law; they provide ways of legitimating a child, such as through subsequent marriage of the parents or through an act of recognition by the father. Modern statute law has brought the positions in different systems closer together and removed some of the worst features of the doctrine of legitimacy. Legitimacy is a concept of diminishing importance in modern law, and even countries that still retain it have usually modified it. They have done so by basing support obligations on parentage rather than on a legally valid marriage and by giving rights of intestate succession to children born out of wedlock. By the legal devices of legitimation and adoption and by other means, the difference between the legal status of a legitimate and that of an illegitimate child has been narrowed.

Illegitimacy is frequently associated with poverty; a contributing factor in this has been the tendency to exclude the child by law and social circumstances from what the community regarded as a customary and respectable family structure. The illegitimate child has usually lacked the financial support available in the conventional family group. Sometimes the laws have been designed to prevent the cost of support from falling on those not biologically responsible for the birth. Thus, English legislation of 1576 provided that an order could be made on the putative father for the maintenance of a bastard by the parish (the local government). The thrust of modern law-reform proposals, in general, is that the welfare of all children should be a matter of honest and effective public concern, made mandatory by statutory provisions.

Adoption. In modern societies, adoption tends to be associated with illegitimacy because adoption of the children of unmarried mothers has become common, although in some jurisdictions there is also a considerable number of married parents who offer their children for adoption. The ordinary legal principle is that the consent of a natural parent (or guardian) is required for an adoption order by a court. This consent may be dispensed with if the correct person cannot be found or has proved to be an uninterested or cruel parent. An emerging problem for family law in some countries is whether courts or public agencies should be able to effect the transfer of a child from the custody of its parents on the ground of what is best for the welfare of the child.

Adoption in Roman law

Adoption in the older legal systems (as in Roman law) was treated mainly in terms of succession law. It provided a way of introducing an outsider into a family group and so bringing him or her within the scope of the succession rules. In modern systems, succession rights and other obligations and rights in cases of adoption are usually treated by analogy with those of legitimate children; in some systems there is an explicit equation with legitimate children.

Education. The rapid development of education in the 19th and 20th centuries has had dramatic effects upon the family and upon the rights and obligations of family members. Until the latter part of the 19th century, even in highly developed countries, the organized education of children of the poorer classes tended to be casual or nil. Since then, the powers of a father to determine the upbringing of his child have declined before the advance of public education and the complex legislation and financing on which it rests. Today the pattern in some parts of the world is compulsory education up to the late teens, with extensive opportunities for higher education into the early 20s and perhaps later. Present tendencies seem to be toward even longer and further involvement with the educational process. If this trend continues, the educational systems of some countries might even become child-rearing systems providing foster homes, boarding houses, children's villages, and various health and welfare facilities. The effect on family law may be to reduce the importance of the biological link between parent and child.

Decision making. The older law in many countries regarded decision making in regard to children as internal to the family, an area in which the courts should not intervene except in cases of serious child abuse or the like. In the English common law, for example, there are decisions of the latter part of the 19th century in which this doctrine of the "family veil" was carried to considerable lengths by giving an autocratic position to the father during his lifetime, and even longer, if a testamentary guardian was appointed upon his death. In most primitive societies, customary law gave similar authority to the father, although sometimes the custody and training of girls was the special province of the mother. In modern law, the power of the father yielded to the principle that the welfare of the child is paramount; but this relaxation has raised important and difficult questions. The prevailing view is that the courts should take jurisdiction and intervene in family decision making when injustice, oppression, or cruelty might result if they did not. The consensus seems to be that it would be an extreme and undesirable principle to make parent–child relations wholly private and exclude the jurisdiction of the courts, but that it would also be extreme and undesirable to have no private domain of decision making and to bring all family disputes to court. The practical rule lies between the extremes; the application of such a rule is uncertain, and there are bound to be differences of opinion.

Traditional authority of the father

A variant of this problem is that of determining the boundaries between private decision making in a family and decision making by public authorities and services, such as child welfare officials. Here the question is to what extent the public authorities ought to share in the bringing up of children. This is a policy issue of great difficulty; in modern times, the courts have tended to intervene more than formerly in cases in which children are neglected, abused, delinquent, and so on.

Questions of custody. Cases can be cited to show the difficulty of reaching agreement among judges and others as to what constitutes the "best interests" and "welfare" of a child. The Supreme Court of Canada has supported the principle that a natural parent, such as an unmarried mother, should not be denied custody of her child merely because applicants wishing to adopt the child offer better material prospects or a two-parent instead of a one-parent household. Other views maintain that a young unmarried mother is, in general, not a suitable custodian of her newborn child and that therefore public intervention leading to adoption is usually in the child's best interests. Another disputed question is whether a difference of religion between a natural parent and an adoptive parent, or between two natural parents, is against the interests of the child. Various shades of opinion have been expressed: for example, that failure to raise a child in a particular religion may stunt its spiritual development; or that a change of religious environment could be upsetting to a child already accustomed for some years to a certain religion.

Questions of custody cannot be determined solely by deduction from a rule of law. They require the exercise of judicial discretion that takes account of all the relevant circumstances, which may be very complex. In divorce cases the situation is often a de facto one: separation of the parents has taken place some time before the legal proceedings, and the child is already in the custody of one of them, so that the divorce decree may do no more than regularize in law what has already happened to the child in fact. Some common-law courts have on occasion ordered joint custody, whereby the noncustodial spouse is involved, together with the custodial spouse, in decision making regarding the welfare and upbringing of the child. Another development of growing importance is the use of some form of family counselling in questions of custody of children. The basic argument in favour of this is that a custody plan worked out with the help of mediation and agreed to voluntarily by the parents is likely to have greater success than a custody judgment imposed on the parents after litigation.

MARRIAGE

The history of marriage is bound up with the legal and economic dependence of women upon men and the legal incapacities of women in owning and dealing with property. In Babylonian law, for example, one characteristic of a "legal wife" was that she brought property to the marriage (as a contribution to the support of the new family). In *The Story of Civilization* the author Will Durant asks what "changed virginity from a fault into a virtue" and answers the question: "Doubtless it was the institution of property. Premarital chastity came as an extension, to the daughters, of the proprietary feeling with which the patriarchal male looked upon his wife. The valuation of virginity rose when, under marriage by purchase, the virgin bride was found to bring a higher price than her weak sister; the virgin gave promise, by her past, of that marital fidelity which now seemed so precious to men beset by worry lest they should leave their property to surreptitious children."

Marriage and its relation to property

Before there was a developed law of wills, there would be a distribution of property upon the death of a paterfamilias. The property taken by a daughter on marriage may have been to compensate for her not being in the family group at the next such distribution. It was also customary for the man to make gifts to his bride, either in property or by giving services to the bride's family, as a token of the seriousness of his intentions.

Marriage as a transfer of dependence. In systems in which the females are legally and economically dependent within a family hierarchy, the juridical essence of marriage is the transfer of the woman from control by her own family to control by her husband. Marriage customs of many times, countries, and religions exhibit this principle in a variety of forms, for example, in certain kinds of Roman marriage, in marriages among the Japanese samurai, in the traditional Chinese marriage, in the Hindu marriage based on the joint family, in rabbinical law, in Muslim law, and in Germanic and Celtic customary law. The Germanic traditions were imported into England, where they combined with Norman concepts to become the basis of the English common law of marriage. The Germanic law provided, at least in higher class families with property, for a payment by the bridegroom for the transfer of the *Mund* (responsibility for, and power over, the woman); for a settlement on the groom by the bride's family; and for a so-called *Morgengab,* which may have represented the completion of the settlement. The giving of a ring had a symbolic role in many kinds of wedding and betrothal ceremonies. The word wed derives from the Anglo-Saxon word for security given to bind a promise. The property used as security was not necessarily transferred but given symbolically (*i.e.,* the ring). In a modern Church of England wedding service, the giving of security is reflected in the words "With this ring I thee wed," and the settlement of property in the words "and with all my worldly goods I thee endow." The minister has previously asked, "Who giveth this woman to be married to this man?" and, on "receiving the woman at her father's or friend's hands," proceeds with the ceremony. This "giving away" of the woman by her family reflects the transfer of the *Mund* to the bridegroom. In some systems the marriage forms may have a "bride purchase" origin, in the sense of compensation to her family (although there are differences of opinion as to the meaning of the customary forms); this was true in certain kinds of marriage in the earlier Roman republic, in Babylonian or Aramaic marriages, in early Arabic marriages, in certain Chinese unions (at least with regard to concubines, in which cases the transaction was more openly a purchase from the girl's parents), in customary marriage in some parts of Africa (*e.g.,* Nigeria, Ghana, Kenya), and in customary marriage among the nomadic tribes of Siberia (*e.g.,* the Kirgiz or Yakuts).

The ancient concept of marriage in many legal systems is that of a transaction between families (and this has sometimes persisted to the present day). Although the consent of the bride and bridegroom was almost always formally required, it may be questioned how real the consent was in the case of a child bride or in marriages between parties who did not see each other beforehand. Go-betweens and marriage brokers have been part of the marriage customs of many countries, especially in the East. The go-between and the professional marriage broker still have a following in some countries. Some have suggested that computer "matching" for marriage may become a modern development of the go-between concept.

Modern marriage law

Marriage as a voluntary relationship. The modern idea of marriage, which is becoming almost universal, is a voluntary exchange of promises between the man and the woman. Even though a marriage may involve substantial decisions as to property, these matters now tend either to be automatic (when there is no marriage contract) or to be formalized separately from the marriage ceremony. The ceremony itself is normally an exchange of consents accompanied by religious observances or a civil ceremony (or both). The purpose of the legal formalities is to differentiate the relationship from concubinage and to create certain recognized legal incidents such as maintenance, custody of children, rights under matrimonial regimes, intestate succession, claims under life-insurance policies and pension funds.

Legal limitations on marriage. In earlier legal systems, especially in Asia, the woman's consent was often unnecessary or of minor importance; the marriage negotiations took place between the woman's father and the man or his family. Voluntary consent of the parties became important in Roman times. Roman law during the period of the empire distinguished between an agreement for present marriage and an agreement for future marriage (*sponsalia per verba de praesenti* and *sponsalia per verba de futuro*). This distinction was taken over by Christianity, and a promise for marriage *per verba de futuro* was supported by a guarantee or "deposit" payment or by a penalty clause in a marriage contract.

Engagement. The view of the canon law of Christianity was that an engagement incapacitated a person from marriage to a different party and consequently provided ground for annulment of a marriage. This raised an issue that has troubled the civil lawyer but apparently not the common lawyer; *i.e.,* whether penalties, forfeiture provisions, damages, and the like for breach of engagement or betrothal are consistent with the exchange of voluntary consent at the marriage ceremony. Thus, French law has been led to reject an action of breach of promise (while permitting an action in delict—that is, on the ground that one party has been wronged). The common law, on the other hand, allows claims for breach of promise, although the modern tendency is to eliminate this form of action by statute.

The public interest. It has been difficult to delineate the boundaries between public and private interest in marriage law. The public interest is involved in the prevention of clandestine marriages; in requiring a license or the publication of banns as a condition precedent to marriage; in requiring parental consent for marriages between persons of certain ages; and in providing for the registration of marriages in a public manner. In practice, however, the marriage laws are often a mixture of functional administrative provisions (such as the requirement for registration and health certificates), old customs, and religious ceremonies. Marriage statutes were introduced in modern times to combat the danger of clandestine marriages, which were possible under the old law in Europe and England by some form of mutual consent. In addition to direct proof of consent, a clandestine marriage could be established by engagement followed by intercourse (*matrimonium subsequente copula*) or by habit and repute marriage (evidence of acceptance in the community as being married persons). Clandestine marriage was significant at a time when a man could acquire control over the property of a woman, including absolute ownership of much of it. The emancipation of women has put an end to the economic advantages of the clandestine marriage, but the legislation to which it gave rise has left an impress on the statute books.

Clandestine marriage

Age. In order to satisfy the requirement of a voluntary consent to a marriage, a party must have reached an age at which he or she is able to give a meaningful consent, and it is also implied that a person may be legally disqualified on mental grounds from having capacity to marry. Marriages of young children, negotiated by their parents, are prohibited in modern societies. Historically, the attitude of the English common law was that a person under seven years lacked the mental ability to consent to marriage, and that between seven years and puberty there could be consent but not a consummated marriage. At common law, therefore, the marriage of a person between the ages of seven and 12 or 14 was "inchoate" and would become "choate" on reaching puberty, if no objection was raised. Most modern legal systems provide for a legal minimum age of marriage ranging from 15 to 18 years. Some systems require parental consent to marriage when the parties are above the minimum age but below some other age, and failure to obtain this may be a ground for annulment. Parental consent has a long historical tradition, and there have been systems in which the girl's consent was virtually unnecessary. It is difficult to say, therefore, whether modern provisions have a valid social function or are the flotsam of older ideas on marriage.

Relationship. Other laws forbid marriage between persons having certain ties of relationship, either of blood or of marriage. "Forbidden degrees" of one sort or another exist in most social groups. The rules against marrying close relatives are sometimes said to be directed against the dangers of inbreeding, but this does not explain the prohibition against unions between persons who are related only by marriage. In classical Chinese society, marriage was regarded as a linking of different families, and the traditional pattern was exogamy (marriage outside the family). In ancient Egypt, on the other hand, where the pharaoh was deified, marriages within the blood were considered desirable in order to preserve its purity. Marriages between cousins are apparently encouraged in some Arab countries, perhaps to strengthen family ties and to keep the property together.

Religion. Religion has had a strong influence on marriage law, often providing the main basis of authority. Hindu family law, which goes back at least 4,000 years (and may be the oldest known system), is a branch of dharma—that is, the aggregate of religious, moral, social, and legal duties and obligations as developed by the

*Smṛti*s, or collections of the law. Islāmic and Jewish family law also rests on spiritual authority. Religious courts have had jurisdiction over family matters in various countries, and in some countries they still possess it. Some modern religious courts retain only their spiritual jurisdiction over marriage and divorce; their judgments have no standing in the secular law. In some Roman Catholic and Greek Orthodox Christian marriages and also in Muslim and Jewish marriages, the application of the religious law is regarded as binding upon persons belonging to the faith. Where religious texts provide the literal authority for legal principles, as in Islāmic law, it may be necessary to reinterpret the texts in order to reform the law. This raises complex issues in those Muslim countries where there are movements for greater equality of the sexes.

ECONOMIC ASPECTS OF FAMILY LAW

The variety of approaches to marital property

The property of husband and wife. The comparative legal history of marital property, viewed in broad perspective, consists of a period stretching back for about 4,000 years, during which a husband was generally regarded as a quasi-guardian of his wife, who was dependent upon him economically and legally. The English common law removed the separate legal personality of a woman when she married and merged it in that of her husband, though she regained it if she became a widow. Her husband acquired extensive rights to the administration and ownership of her property, including full ownership (with no obligation even to give an accounting) of any moneys she received from employment or business. Until quite recently, the only property of which a Hindu woman was the absolute owner was her *strīdhana,* consisting mainly of wedding gifts and gifts from relatives. Muslim women have traditionally owned and managed their own property. In Japan, before enactment of the Meiji Civil Code of 1898, all of the woman's property such as land or money passed to her husband except for personal clothing and a mirror stand. In early Vietnamese customary law, the property contributions of both spouses formed a common mass that was administered jointly and then divided, together with acquisitions made during their marriage, between the spouses and their heirs. In ancient Burmese law, all of the property of the spouses comprised a common mass that was their joint property but was administered by the husband, who exercised extensive powers. In 13th-century France there was a concept of "community" on the lines of a partnership between the spouses; but by the 16th century, French husbands had secured the *puissance maritale* ("marital power") that gave them power over the disposal of property. In ancient Hungarian law, the bride usually brought property to the marriage, and a regime with a form of dowry persisted until World War II. The law of imperial Russia permitted a wife to own and deal with property independently of her husband—an attitude that differed from its treatment of women in other respects. A Roman wife, in some marriage forms, had a position of independence in regard to her property that was unusual for that era. In Celtic law, the man gave property to the woman's family; according to Brehon law (the ancient law of Ireland), the payment could be made by annual installments over 21 years (the woman's father kept the first installment, two-thirds of the second, half of the third, and so on, the remainder going to the wife).

Brehon law

The emancipation of women, which occurred in many countries during the latter part of the 19th century and the first part of the 20th, had a profound effect upon family law and marital property. The Scandinavian countries made radical reforms in their marital property laws in the 1920s; they introduced a new type of matrimonial regime in which the spouses retain independent control of their property except for some items for the disposal of which the consent of the other spouse is required, but the combined remaining matrimonial property is divided at the termination of the regime. This has been influential in the reforms of other countries. The Federal Republic of Germany introduced legal equality of the sexes as a constitutional principle in the 1950s, followed by substantial amendments to the civil code with respect to the financial and property relations of spouses; these included a new matrimonial regime on sharing the value of the economic gains of marriage, analogous in broad principle to the Scandinavian reforms but containing new features. The French civil code received major revisions with respect to the matrimonial regimes in 1965. In 1969 the civil code of Quebec was revised to give full capacity to married women; it also created a new matrimonial regime, described as a partnership of acquests (that is, property acquired by the spouses after their marriage). In 1950 the People's Republic of China enacted a comprehensive marriage law including provisions giving the spouses equal rights with regard to ownership and management of marital property. The Soviet Union issued the Fundamentals of Legislation on Marriage and the Family in 1968, and a marriage and family code, providing for a form of community of acquests, was enacted in 1969 for the Russian S.F.S.R. The German Democratic Republic introduced a code of family law in 1965 based on principles of equality of the sexes in financial and property matters. Czechoslovakia's code of family law, enacted in 1964, introduced a concept of joint ownership with an equal share in management. Community sharing systems have been introduced by codes in Romania (1954) and Poland (1964). Substantial changes in the property capacity of Hindu women were made by the Hindu Succession Act of 1956.

In the 1970s the reform of the treatment at law of marital property became an important issue in various other countries, including England and Scotland, Belgium, Israel, and Canada. There was a quantity of new legislation on matrimonial property, especially in the common-law countries, and in some cases the process of reform and legislative change has continued.

Maintenance and support. The law of maintenance and support has differed from that of marital property in most countries. A widow, for example, normally receives some share in her husband's estate upon his death. Some systems of law require that dependents receive a compulsory share in the estate or dependent's relief or family provision (that is, financial support out of the estate for a dependent in straitened circumstances). Most systems of law have traditionally regarded financial support as the responsibility of a husband and a father (to which any dowry or property from the wife was considered a contribution). But in a hierarchical structure, such as the Greek or Roman family, the responsibility might rest on the paterfamilias, if different from the husband. In Hindu law, the male members of a joint family, together with their wives, widows, and children, are entitled to support out of the joint property.

Traditional laws of support

The influence of legislation. Social welfare legislation and the principle that a child's welfare is paramount have added a dimension and an inconsistency to the traditional principle of paternal responsibility. The new dimension is a public one and implies that society has an ultimate responsibility to see that children receive at least a minimum standard of maintenance. In some countries—for example, the United States, Canada, and various European countries—attempts have been made to combine parental and public responsibility for the child's welfare.

The enforcement of the legal obligation of a parent to maintain a child runs into a number of difficulties in law and practice. The father may be too poor to support his child, or he may be impossible to locate, or he may already be in prison for refusal to pay. A wife may be reluctant to sue her husband (for personal reasons and perhaps in the hope of a reconciliation), and if she does not do so, the child will be deprived of financial aid. Where there are social welfare programs supported by taxes, efforts may be made to protect the tax revenues by, for example, requiring a deserted wife to sue her husband as a condition of receiving welfare payments. Sometimes the authorities institute criminal or contempt proceedings against the husband. But in the North American and British experience, the payment record of obligants on maintenance orders is generally poor; the money recovered is usually inadequate; and the cost of enforcement may even approach the sums collected. It is not difficult to see why a high proportion of one-parent families exist in poverty even in countries with highly developed economies.

Working wives. The introduction to the British Census of 1851 stated: "The duties of a wife, a mother, a mistress of a family, can only be efficiently performed by unremitting attention; accordingly it is found that in districts where the women are much employed from home, the children and parents perish in great numbers." Even assuming that were true, much has changed since then. Most modern countries provide that a husband and wife have mutual obligations of financial support according to their means, aiming at a common standard of living for them both. The older principle was that the husband supported the wife in return for obtaining most of her property or becoming *chef de la famille et de la communauté* in a community-property system. Some common-law systems are a curious mixture of old and new principles. A high proportion of married women, in Western countries at least, are now employed outside the home, and the trend is expected to continue and probably accelerate. Two results of this trend are that (1) more married women now own some money and property and (2) on separation, divorce, or widowhood, a woman is more likely to be employed and so not dependent on support.

Separation of marital property. Reforms in marital-property laws have tended to reflect the wishes of spouses and their families, rather than traditional customs, religious attitudes, and dogmatic formulas. The French civil code of 1804 began a European pattern of giving spouses a choice of matrimonial regime: the codifiers were confronted with a variety of customary laws in different parts of the country, and, not wishing to impose one of them, they included alternatives in the code, designating one, the Custom of Paris, as the legal regime that would apply if the parties did not select another in a marriage contract. In common-law countries, the tendency has been to favour separation of property—a tendency resulting more by accident than by intention. This has come about because most of these countries adopted married women's property legislation that removed the incapacity of a married woman to make contracts and deal with her property, thus destroying the existing system by which the wife's property passed into the control of the husband. No new matrimonial system was constructed, so that the spouses were placed in the position of separate individuals so far as property was concerned. They can, of course, draw up marriage contracts or settlements to express their own wishes, but such contracts are now rare. The laws of the Communist countries usually provide a matrimonial regime, intended to promote the social and political policy of the government.

Alternatives in marital property law

In countries where the spouses are given a choice of regime, many of them do not exercise their option. A survey made in France in 1963–64 indicated that 76 percent of the couples made no marriage contract and therefore were subject to the legal regime. In Quebec, on the other hand, before the legislation in 1969 on marital property, more than 70 percent of marrying couples signed contracts for separation of property; part of the explanation for this may be that Quebec is surrounded by jurisdictions in which the common law prevails.

Even in modern times, in most cases husbands and wives differ in their potential for acquiring property. In separation of property, husbands and wives owning property and dealing with each other will be in the same position as unmarried adults. There are, however, grounds for distinguishing marital property questions from ordinary property questions, because persons who cohabit on a domestic basis share a common standard of living and usually also the benefits of each other's property. A major element in many marriages is the raising of children, and the traditional female role, requiring her full-time presence in the home, places the married woman at a disadvantage so far as earning money and acquiring property are concerned. It is inconsistent of society to encourage a woman to take the domestic role of wife and mother, with its lower money and property potential, but in property matters to treat her as if she were a single person. It is also inconsistent to place upon the husband the sole responsibility for maintaining his wife and children, if his wife has regular employment outside the home. When the marriage is dissolved, if the wife has not been regularly employed and now enters the labour market on a full-time basis, she may be at a considerable disadvantage as far as salary and pension rights are concerned.

Inconsistent social attitudes

Community property. A marital-property system should try to balance two sets of interests: the interests of the spouses and the interests of third parties such as purchasers, creditors, and business partners. Community-property regimes emphasize the first but are less attractive in terms of the second, because the property is tied up in the community and is subject to the interests of both spouses, whereas the third party may be dealing with only one of them. Separation of property gives property independence to each spouse, but it does not provide for sharing unless the spouses place items of property under joint ownership. Consequently, there has been a trend in many countries toward new regimes giving the husband and wife independence in dealing with property but also providing rules for a division of net assets on liquidation of the marriage. The first country in Europe to initiate this type was Sweden, in 1920.

In some common-law countries, certain items of property have received special treatment. Examples are the matrimonial home in English law (under decisions of the courts beginning around 1950) where there has been concern about a wife's being evicted by a purchaser or mortgagee from her husband, and also about division of proceeds of the sale when both spouses have contributed something to the purchase, or where one has done improvements on the other's property, or where the husband's payments toward the purchase have been possible because the wife's money was used for the day-to-day domestic needs of the family, and so on. In parts of the United States and Canada, there have been "homestead" laws providing that one spouse cannot dispose of or encumber the home without the consent of the other, that the use goes to the widow or family on the owner's death, and that the home cannot be sold in execution.

Tort actions between spouses. In English common law, as amended by the property legislation of the 19th century, a husband could not sue his wife in tort (that is, for a wrongful civil act not arising from contract), and she could sue him only in respect of damage to her separate property. This has been variously explained as stemming from the doctrine of the unity of the legal personalities of husband and wife (so that the plaintiff and the defendant are the same legal person) or from the belief that it would be disruptive to the family to allow damage suits between spouses. The modern tendency is to permit delict or tort action between spouses. This seems consistent with the fact that many damage suits, such as automobile accident claims, are covered by insurance, and the litigation in such cases is therefore between two insurance companies with the spouses as nominal parties.

Movements exist in North America and Europe favouring the recognition of a "no-fault" basis for certain delict or tort proceedings; this would transfer the emphasis in such actions to securing compensation for the person who suffered the damage, rather than determining whether the plaintiff can establish a cause of action (which usually means proving fault).

Co-ownership. Some marital-property systems that are basically separation of property have modifications for the situation in which, for example, an asset has been acquired by contributions from both spouses with the intention that both will benefit from its purchase—as with a home, furnishings, an automobile, a joint bank account, or joint investments. But the attitudes of husbands and wives as to their property after a marriage has broken down may be quite different from their intentions when an asset was acquired. There are decisions of the English courts that imply that in some of these circumstances, at least, the net value of the asset should be divided equally on the maxim that "equality is equity." The boundaries of this principle, however, are not at all certain.

Japanese marital-property law was revised in 1947, and the present legal regime is a modified form of separation of property. Under this regime, property to which only one spouse has title, but in the acquisition of which both have really cooperated during their marriage, is considered substantially co-owned. The civil code has been interpreted to the effect that substantially co-owned property is attributed to the title holder in a question involving third parties and to both spouses in a question between the spouses themselves.

DIVORCE

A marriage can terminate as a human relationship before it is dissolved by law. Quite often the court rulings as to property and the custody of children will merely confirm arrangements that have already been made by the parties concerned. In the United States and Canada, 80 to 90 percent of divorce proceedings are undefended; often the parties have made provisional arrangements about property, and one of them already has custody of the children. Before a union can be dissolved by divorce, there must have been a valid marriage. If a marriage has been imperfectly constituted in law, it may be annulled; grounds for annulment include lack of capacity, no reality of consent by the parties, a vitiating defect in the marriage ceremony, or the subsequent discovery of a defect such as inability to consummate the marriage.

In old legal systems, marriage was conceived as the transfer of a woman from the power of her family to that of her husband under terms usually specified in the marriage contract. The standard method of dissolving a marriage if both parties were alive was repudiation, resulting usually in the return of the woman to the power of her family. Repudiation has had a considerable history; it has strongly influenced marriage law in Muslim, Jewish, Chinese, and Japanese law. In Muslim law, repudiation can occur without proof of legally designated fault or a breakdown of the marriage. In practice, of course, there are checks on the too facile use of this power by a husband, such as objection from the wife's family, the obligation to repay the value of a dowry, or religious disapproval. In Roman marriage law, unilateral repudiation at will was permitted, and this freedom existed for some time in the early Christian Era. The concern of the Roman law was for solemnity rather than grounds, and unilateral divorce was by a notification of repudiation before seven witnesses.

Indissoluble marriages

At the other extreme from repudiation at will is the sacramental view of marriage (as in the teaching of certain Christian churches) that a marriage may not be dissolved during the joint lives of the spouses. Formerly, a Hindu marriage was indissoluble (except by caste custom) and might be eternal.

Between the extremes of repudiation at will and indissoluble marriage, there are various divorce formulas: divorce for fault, such as adultery, desertion, cruelty, or imprisonment; divorce on grounds analogous to frustration of contract, such as incurable insanity subsequent to the marriage or disappearance of the spouse; divorce by mutual agreement; and divorce on the ground that the marriage has broken down. The variety of laws and attitudes with respect to divorce is bewildering. In comparing divorce laws, it should be remembered that the rates of divorce and of marriage breakdown are different; the latter are hard to ascertain, although the breakdown rate obviously exceeds the divorce rate. If the grounds for divorce are widened, then the divorce rate will rise; if marriage is made indissoluble, the divorce rate will, of course, be zero. In many countries the trend has been toward more liberal divorce legislation (with a consequent rise in divorce rates).

A complicating factor in divorce law is the question of giving recognition to foreign divorces. The divorce laws of countries and states differ, and so do their rules for recognition of divorces elsewhere. A person living in a jurisdiction in which divorce is difficult to obtain may be able to go to another in which divorce laws are more liberal and obtain a dissolution of the marriage that will be recognized in the first jurisdiction. A feature of private international family law is the "limping" relationship—when a person is regarded as married by country X and as single by country Y, and a child as legitimate by country A and as illegitimate by country B. One reason why a country may restrict the recognition of divorces is that there are a number of jurisdictions in which divorce is granted on liberal grounds and with only nominal connections between the spouses and the divorce-granting jurisdiction (sometimes giving the impression of "divorce mills" that are operated for commercial reasons).

Some divorce laws provide for conciliation efforts (as in Sweden, Australia, and Canada), but these do not seem to have had any significant effect on divorce rates. In Chinese law, there is a long tradition of conciliation in many legal areas, including family law. But divorce stems from the desire to end an intimate human relationship that may have existed for some years. It is not an ordinary dispute at law; it has little in common with the interpretation of a business deal, a tax claim, a criminal charge, or other legal questions that can be presented fairly precisely. In a divorce, only the spouses can really know the differences between them, and neglect of this distinction can produce reasoning by false analogy.

FAMILY COURTS

In some countries there are special courts for family matters, set up in pursuit of religious, political, or social objectives; these include the Christian, Muslim, and Jewish ecclesiastical courts. There are also people's courts and conciliation courts, particularly in Communist countries.

Another approach has been to establish social courts that have a functional relation to the legal problems affecting families. Such problems include marriage, divorce, annulment, matrimonial regime, maintenance of spouses or of children, adoption, custody of children, legitimacy, filiation proceedings, juvenile delinquency, care and protection of children, assault on a spouse or a child, torts between spouses, marriage contracts, and judicial separation. Although these are the problems that produce the largest volume of private law litigation in most countries, family law has not, in many countries, been given a corresponding priority by the regular courts.

Character of family law

Those who favour special courts for family matters argue that family law is concerned with human relationships that require a judicial environment different from that of ordinary civil actions. The facts of the dispute in a family matter may not be as significant as the underlying problems (financial difficulties, health, addiction to drugs or alcohol) that have projected the issue. Another argument favouring family courts is that a high proportion of family proceedings are noncontentious or undefended; for example, proceedings concerning adoption and children in need of care normally require not so much the application of law as an inquiry into what is in the best interests of the child. In family matters, moreover, the court has need of ancillary services—social workers, probation officers, liaison with various social agencies. Since children and young people are often involved, there is need of special legal officers to present inquiry material to the court or to represent the interests of the children (which may conflict with the positions taken by their parents).

A number of countries have established special courts for cases relating to children and young people (sometimes with lay members) and special procedures for the disposition of such cases. Less progress has been made in the area of comprehensive family courts. One reason may be that family law can be less rewarding and more time-consuming as compared with more lucrative and prestigious fields of law.

It is sometimes argued that judges should be given a wide discretion in family cases. This seems to have been done in the family codes of eastern Europe and the People's Republic of China, which are loosely constructed with statements of politico-legal principles and leave much leeway to the judges or conciliators. In the United Kingdom and the United States the proposal has been made that in a divorce case, for example, the court should have discretion not only as to the custody of children but also as to arrangements for maintenance and disposition of property; the court should do what it thinks just, having regard to the history of the marriage and the behaviour of the spouses. Against this it is argued that such discretion would tend to turn tribunals into courts of morals in which the personal views of judges could prevail in the absence of applicable legal rules.

BIBLIOGRAPHY. Family law encompasses an enormous literature. Further, the principal legal writings in each country are in the language of that country, and there has been little translation of law books or articles. The following are a few suggestions for further reading, including a number of titles relating to the complex subject of comparative marital property.

Comparative law is the focus of MARY ANN GLENDON, *State, Law, and Family: Family Law in Transition in the United States and Western Europe* (1977), and a successor work, *The Transformation of Family Law: State, Law, and Family in the United States and Western Europe* (1989); JOHN EEKELAAR and SANFORD N. KATZ (eds.), *Marriage and Cohabitation in Contemporary Societies: Areas of Legal, Social, and Ethical Change* (1980); M.T. MEULDERS-KLEIN and JOHN EEKELAAR (eds.), *Family, State, and Individual Economic Security,* 2 vol. (1988), in English and French; JEAN PATARIN and IMRE ZAJTAY (eds.), *Le Régime matrimonial légal dans les législations contemporaines,* 2nd ed. (1974); and the journal *Revue internationale de droit comparé* (quarterly).

Works dealing with civil-law systems include VIRGILIO DE SÁ PEREIRA, *Direito de familia,* 2nd ed. (1959); MARCEL BRAZIER, *Le Nouveau Droit des époux et les régimes matrimoniaux* (1965); F.H. LAWSON, A.E. ANTON, and LIONEL NEVILLE BROWN (eds.), *Amos and Walton's Introduction to French Law,* 3rd ed. (1967); JEAN PATARIN and GEORGES MORIN, *La Réforme des régimes matrimoniaux,* 4th ed., vol. 1, *Statut fondamental et régime légal* (1977); JOACHIM GERNHUBER, *Lehrbuch des Familienrechts,* 3rd rev. ed. (1980); ANDRÉ COLOMER, *Droit civil: régimes matrimoniaux* (1982); GÜNTHER BEITZKE, *Familienrecht,* 25th ed. (1988); and JOSÉ CASTÁN TOBEÑAS, *Derecho civil español, común y foral,* vol. 5, *Derecho de familia,* 10th ed. rev. and updated by GABRIEL GARCÍA CANTERO and JOSÉ MA. CASTÁN VÁZQUEZ (1995).

General studies of common-law systems are RONALD H. GRAVESON and FRANCIS R. CRANE (eds.), *A Century of Family Law, 1857–1957* (1957); MARY ANN GLENDON, *The New Family and the New Property* (1981); JOHN EEKELAAR, *Family Law and Social Policy,* 2nd ed. (1984); MICHAEL D.A. FREEMAN (ed.), *The State, the Law, and the Family: Critical Perspectives* (1984); HOMER H. CLARK, JR., *The Law of Domestic Relations in the United States,* 2nd ed., 2 vol. (1987); LAURENCE D. HOULGATE, *Family and State: The Philosophy of Family Law* (1988); STEPHEN M. CRETNEY and J.M. MASSON, *Principles of Family Law,* 5th ed. (1990); HARRY D. KRAUSE (ed.), *Family Law,* 2 vol. (1992); and P.M. BROMLEY and N.V. LOWE, *Family Law,* 8th ed. (1992).

Works treating the subject of divorce and laws affecting the distribution of marital property include IAN F.G. BAXTER, *Marital Property* (1973); JUDITH S. WALLERSTEIN and JOAN BERLIN KELLY, *Surviving the Breakup: How Children and Parents Cope with Divorce* (1980); W.S. MCCLANAHAN, *Community Property Law in the United States* (1982); LENORE J. WEITZMAN, *The Divorce Revolution: The Unexpected Social and Economic Consequences for Women and Children in America* (1985); HERBERT JACOB, *Silent Revolution: The Transformation of Divorce Law in the United States* (1988); JUDITH S. WALLERSTEIN and SANDRA BLAKESLEE, *Second Chances: Men, Women, and Children a Decade After Divorce* (1989); and STEPHEN D. SUGARMAN and HERMA HILL KAY (eds.), *Divorce Reform at the Crossroads* (1990).

Discussions of child custody and child welfare can be found in JOSEPH GOLDSTEIN, ANNA FREUD, and ALBERT J. SOLNIT, *Beyond the Best Interests of the Child,* new ed. (1979); JEFF ATKINSON, *Modern Child Custody Practice,* 2 vol. (1986); SAMUEL M. DAVIS and MORTIMER D. SCHWARTZ, *Children's Rights and the Law* (1987); ANDREW BAINHAM and STEPHEN M. CRETNEY, *Children: The Modern Law* (1993); and DONALD T. KRAMER (ed.), *Legal Rights of Children,* 2nd ed., 3 vol. (1994).

Reproductive issues and surrogacy are examined in SHEILA MCLEAN (ed.), *Legal Issues in Human Reproduction* (1989); ELAINE SUTHERLAND and ALEXANDER MCCALL SMITH (eds.), *Family Rights: Family Law and Medical Advance* (1990), discussing the impact of rapid scientific change on the law; LARRY GOSTIN (ed.), *Surrogate Motherhood: Politics and Privacy* (1990); and MARTHA A. FIELD, *Surrogate Motherhood,* expanded ed. (1990).

Studies of eastern European systems of family law are KAZIMIERZ GRZYBOWSKI, *Soviet Legal Institutions* (1962, reprinted 1982); EDWARD L. JOHNSON, *An Introduction to the Soviet Legal System* (1969); DOMINIK LASOK, *Polish Family Law* (1968); ENDRE NIZSALOVSZKY, *Order of the Family,* trans. from Hungarian (1968); and ŠTEFAN LUBY (ed.), *Le Droit civil tchécoslovaque* (1969).

Family law in Muslim society is explored in JOSEPH SCHACHT, *An Introduction to Islamic Law* (1964, reprinted 1982); YVON LINANT DE BELLEFONDS, *Traité de droit musulman comparé,* 3 vol. (1965–73); ASAF A.A. FYZEE, *Outlines of Muhammadan Law,* 4th ed. (1974); B.R. VERMA, *Islamic Law—Personal,* 6th ed. rev. by M.H. BEG and S.K. VERMA (1986); C.G. WEERAMANTRY, *Islamic Jurisprudence: An International Perspective* (1988); and MOHAMMAD HASHIM KAMALI, *Principles of Islamic Jurisprudence,* rev. ed. (1991).

Hindu law is discussed in J. DUNCAN M. DERRETT, *Essays in Classical and Modern Hindu Law,* 4 vol. (1976–78); and DINSHAH H. MULLA, *Principles of Hindu Law,* 15th ed. by SUNDERLAL T. DESAI (1982).

Assessments of family law in Asian and African systems are presented in ROBERT LINGAT, *Les Régimes matrimoniaux du sud-est de l'Asie,* 2 vol. (1952–55); ARTHUR TAYLOR VON MEHREN (ed.), *Law in Japan* (1963); J.N.D. ANDERSON (ed.), *Family Law in Asia and Africa* (1968); DAVID C. BUXBAUM (ed.), *Family Law and Customary Law in Asia* (1968), and *Chinese Family Law and Social Change in Historical and Comparative Perspective* (1978); B.P. BERI, *Law of Marriage and Divorce in India* (1982); and HIROSHI ODA, *Japanese Law* (1992).

(I.F.G.B./Ed.)

Faraday

Michael Faraday, who became one of the greatest scientists of the 19th century, began his career as a chemist. He wrote a manual of practical chemistry that reveals his mastery of the technical aspects of his art, discovered a number of new organic compounds, among them benzene, and was the first to liquefy a "permanent" gas (*i.e.*, one that was believed to be incapable of liquefaction). His major contribution, however, was in the field of electricity and magnetism. He was the first to produce an electric current from a magnetic field, invented the first electric motor and dynamo, demonstrated the relation between electricity and chemical bonding, discovered the effect of magnetism on light, and discovered and named diamagnetism, the peculiar behaviour of certain substances in strong magnetic fields. He provided the experimental, and a good deal of the theoretical, foundation upon which James Clerk Maxwell erected classical electromagnetic field theory.

Faraday, oil painting by T. Phillips, 1842. In the National Portrait Gallery, London.

Early life. Michael Faraday was born on September 22, 1791, in the country village of Newington, Surrey, now a part of South London. His father was a blacksmith who had migrated from the north of England earlier in 1791 to look for work. His mother was a country woman of great calm and wisdom who supported her son emotionally through a difficult childhood. Faraday was one of four children, all of whom were hard put to get enough to eat, since their father was often ill and incapable of working steadily. Faraday later recalled being given one loaf of bread that had to last him for a week. The family belonged to a small Christian sect, called Sandemanians, that provided spiritual sustenance to Faraday throughout his life. It was the single most important influence upon him and strongly affected the way in which he approached and interpreted nature.

Faraday received only the rudiments of an education, learning to read, write, and cipher in a church Sunday school. At an early age he began to earn money by delivering newspapers for a book dealer and bookbinder, and at the age of 14 he was apprenticed to the man. Unlike the other apprentices, Faraday took the opportunity to read some of the books brought in for rebinding. The article on electricity in the third edition of the *Encyclopædia Britannica* particularly fascinated him. Using old bottles and lumber, he made a crude electrostatic generator and did simple experiments. He also built a weak voltaic pile with which he performed experiments in electrochemistry.

Faraday's great opportunity came when he was offered a ticket to attend chemical lectures by Sir Humphry Davy at the Royal Institution of Great Britain in London. Faraday went, sat absorbed with it all, recorded the lectures in his notes, and returned to bookbinding with the seemingly unrealizable hope of entering the temple of science. He sent a bound copy of his notes to Davy along with a letter asking for employment, but there was no opening. Davy did not forget, however, and, when one of his laboratory assistants was dismissed for brawling, he offered Faraday a job. Faraday began as Davy's laboratory assistant and learned chemistry at the elbow of one of the greatest practitioners of the day. It has been said, with some truth, that Faraday was Davy's greatest discovery.

Studies with Sir Humphry Davy

When Faraday joined Davy in 1812, Davy was in the process of revolutionizing the chemistry of the day. Antoine-Laurent Lavoisier, the Frenchman generally credited with founding modern chemistry, had effected his rearrangement of chemical knowledge in the 1770s and 1780s by insisting upon a few simple principles. Among these was that oxygen was a unique element, in that it was the only supporter of combustion and was also the element that lay at the basis of all acids. Davy, after having discovered sodium and potassium by using a powerful current from a galvanic battery to decompose oxides of these elements, turned to the decomposition of muriatic (hydrochloric) acid, one of the strongest acids known. The products of the decomposition were hydrogen and a green gas that supported combustion and that, when combined with water, produced an acid. Davy concluded that this gas was an element, to which he gave the name chlorine, and that there was no oxygen whatsoever in muriatic acid. Acidity, therefore, was not the result of the presence of an acid-forming element but of some other condition. What else could that condition be but the physical form of the acid molecule itself? Davy suggested, then, that chemical properties were determined not by specific elements alone but also by the ways in which these elements were arranged in molecules. In arriving at this view he was influenced by an atomic theory that was also to have important consequences for Faraday's thought. This theory, proposed in the 18th century by Ruggero Giuseppe Boscovich, argued that atoms were mathematical points surrounded by alternating fields of attractive and repulsive forces. A true element comprised a single such point, and chemical elements were composed of a number of such points, about which the resultant force fields could be quite complicated. Molecules, in turn, were built up of these elements, and the chemical qualities of both elements and compounds were the results of the final patterns of force surrounding clumps of point atoms. One property of such atoms and molecules should be specifically noted: they can be placed under considerable strain, or tension, before the "bonds" holding them together are broken. These strains were to be central to Faraday's ideas about electricity.

Faraday's second apprenticeship, under Davy, came to an end in 1820. By then he had learned chemistry as thoroughly as anyone alive. He had also had ample opportunity to practice chemical analyses and laboratory techniques to the point of complete mastery, and he had developed his theoretical views to the point that they could guide him in his researches. There followed a series of discoveries that astonished the scientific world.

Faraday achieved his early renown as a chemist. His reputation as an analytical chemist led to his being called as an expert witness in legal trials and to the building up of a clientele whose fees helped to support the Royal Institution. In 1820 he produced the first known compounds of carbon and chlorine, C_2Cl_6 and C_2Cl_4. These compounds were produced by substituting chlorine for hydrogen in "olefiant gas" (ethylene), the first substitution reactions induced. (Such reactions later would serve to challenge the dominant theory of chemical combination proposed by Jöns Jacob Berzelius.) In 1825, as a result of research on illuminating gases, Faraday isolated and described benzene. In the 1820s he also conducted investigations of steel alloys, helping to lay the foundations for scientific metallurgy and metallography. While completing an assignment from the Royal Society of London to improve the quality of optical glass for telescopes, he produced a glass of very high refractive index that was to lead him, in 1845, to the discovery of diamagnetism. In 1821 he married Sarah Barnard, settled permanently at the Royal Institution, and began the series of researches on electricity and magnetism that was to revolutionize physics.

Discovery of electromagnetic rotation

In 1820 Hans Christian Ørsted had announced the discovery that the flow of an electric current through a wire produced a magnetic field around the wire. André-Marie Ampère showed that the magnetic force apparently was a circular one, producing in effect a cylinder of magnetism around the wire. No such circular force had ever before been observed, and Faraday was the first to understand what it implied. If a magnetic pole could be isolated, it ought to move constantly in a circle around a current-carrying wire. Faraday's ingenuity and laboratory skill enabled him to construct an apparatus that confirmed this conclusion (see Figure). This device, which transformed electrical energy into mechanical energy, was the first electric motor.

This discovery led Faraday to contemplate the nature of electricity. Unlike his contemporaries, he was not convinced that electricity was a material fluid that flowed through wires like water through a pipe. Instead, he thought of it as a vibration or force that was somehow transmitted as the result of tensions created in the conductor. One of his first experiments after his discovery of electromagnetic rotation was to pass a ray of polarized light through a solution in which electrochemical decomposition was taking place in order to detect the intermolecular strains that he thought must be produced by the passage of an electric current. During the 1820s he kept coming back to this idea, but always without result.

In the spring of 1831 Faraday began to work with Charles (later Sir Charles) Wheatstone on the theory of sound, another vibrational phenomenon. He was particularly fascinated by the patterns (known as Chladni figures) formed in light powder spread on iron plates when these plates were thrown into vibration by a violin bow. Here was demonstrated the ability of a dynamic cause to create a static effect, something he was convinced happened in a current-carrying wire. He was even more impressed by the fact that such patterns could be induced in one plate by bowing another nearby. Such acoustic induction is apparently what lay behind his most famous experiment. On August 29, 1831, Faraday wound a thick iron ring on one side with insulated wire that was connected to a battery. He then wound the opposite side with wire connected to a galvanometer. What he expected was that a "wave" would be produced when the battery circuit was closed and that the wave would show up as a deflection of the galvanometer in the second circuit. He closed the primary circuit and, to his delight and satisfaction, saw the galvanometer needle jump. A current had been induced in the secondary coil by one in the primary. When he opened the circuit, however, he was astonished to see the galvanometer jump in the opposite direction. Somehow, turning off the current also created an induced current in the secondary circuit, equal and opposite to the original current. This phenomenon led Faraday to propose what he called the "electrotonic" state of particles in the wire, which he considered a state of tension. A current thus appeared to be the setting up of such a state of tension or the collapse of such a state. Although he could not find experimental evidence for the electrotonic state, he never entirely abandoned the concept, and it shaped most of his later work.

Faraday's apparatus for demonstrating the circular field of magnetic force around a current-carrying conductor. An electric current passes through two beakers of mercury, each containing a cylindrical bar magnet. One magnet (left) is freely pivoted, and the upper end rotates about the wire when the current is flowing. The other magnet (right) is fixed, and the pivoted wire rotates about it.

In the fall of 1831 Faraday attempted to determine just how an induced current was produced. His original experiment had involved a powerful electromagnet, created by the winding of the primary coil. He now tried to create a current by using a permanent magnet. He discovered that when a permanent magnet was moved in and out of a coil of wire a current was induced in the coil. Magnets, he knew, were surrounded by forces that could be made visible by the simple expedient of sprinkling iron filings on a card held over them. Faraday saw the "lines of force" thus revealed as lines of tension in the medium, namely air, surrounding the magnet, and he soon discovered the law determining the production of electric currents by magnets: the magnitude of the current was dependent upon the number of lines of force cut by the conductor in unit time. He immediately realized that a continuous current could be produced by rotating a copper disk between the poles of a powerful magnet and taking leads off the disk's rim and centre. The outside of the disk would cut more lines than would the inside, and there would thus be a continuous current produced in the circuit linking the rim to the centre. This was the first dynamo. It was also the direct ancestor of electric motors, for it was only necessary to reverse the situation, to feed an electric current to the disk, to make it rotate.

The first dynamo

While Faraday was performing these experiments and presenting them to the scientific world, doubts were raised about the identity of the different manifestations of electricity that had been studied. Were the electric "fluid" that apparently was released by electric eels and other electric fishes, that produced by a static electricity generator, that of the voltaic battery, and that of the new electromagnetic generator all the same? Or were they different fluids following different laws? Faraday was convinced that they were not fluids at all but forms of the same force, yet he recognized that this identity had never been satisfactorily shown by experiment. For this reason he began, in 1832, what promised to be a rather tedious attempt to prove that all electricities had precisely the same properties and caused precisely the same effects. The key effect was electrochemical decomposition. Voltaic and electromagnetic electricity posed no problems, but static electricity did. As Faraday delved deeper into the problem, he made two startling discoveries. First, electrical force did not, as had long been supposed, act at a distance upon chemical molecules to cause them to dissociate. It was the passage of electricity through a conducting liquid medium that caused the molecules to dissociate, even when the electricity merely discharged into the air and did not pass into a "pole" or "centre of action" in a voltaic cell. Second, the amount of the decomposition was found to be related in a simple manner to the amount of electricity that passed

Theory of electrochemistry

through the solution. These findings led Faraday to a new theory of electrochemistry. The electric force, he argued, threw the molecules of a solution into a state of tension (his electrotonic state). When the force was strong enough to distort the fields of forces that held the molecules together so as to permit the interaction of these fields with neighbouring particles, the tension was relieved by the migration of particles along the lines of tension, the different species of atoms migrating in opposite directions. The amount of electricity that passed, then, was clearly related to the chemical affinities of the substances in solution. These experiments led directly to Faraday's two laws of electrochemistry: (1) The amount of a substance deposited on each electrode of an electrolytic cell is directly proportional to the quantity of electricity passed through the cell. (2) The quantities of different elements deposited by a given amount of electricity are in the ratio of their chemical equivalent weights.

Faraday's work on electrochemistry provided him with an essential clue for the investigation of static electrical induction. Since the amount of electricity passed through the conducting medium of an electrolytic cell determined the amount of material deposited at the electrodes, why should not the amount of electricity induced in a nonconductor be dependent upon the material out of which it was made? In short, why should not every material have a specific inductive capacity? Every material does, and Faraday was the discoverer of this fact.

By 1839 Faraday was able to bring forth a new and general theory of electrical action. Electricity, whatever it was, caused tensions to be created in matter. When these tensions were rapidly relieved (*i.e.*, when bodies could not take much strain before "snapping" back), then what occurred was a rapid repetition of a cyclical buildup, breakdown, and buildup of tension that, like a wave, was passed along the substance. Such substances were called conductors. In electrochemical processes the rate of buildup and breakdown of the strain was proportional to the chemical affinities of the substances involved, but again the current was not a material flow but a wave pattern of tensions and their relief. Insulators were simply materials whose particles could take an extraordinary amount of strain before they snapped. Electrostatic charge in an isolated insulator was simply a measure of this accumulated strain. Thus, all electrical action was the result of forced strains in bodies.

The strain on Faraday of eight years of sustained experimental and theoretical work was too much, and in 1839 he suffered a breakdown of his health. For the next six years he did little creative science. Not until 1845 was he able to pick up the thread of his researches and extend his theoretical views.

Later life. Since the very beginning of his scientific work, Faraday had believed in what he called the unity of the forces of nature. By this he meant that all the forces of nature were but manifestations of a single universal force and ought, therefore, to be convertible into one another. In 1846 he made public some of the speculations to which this view led him. A lecturer, scheduled to deliver one of the Friday evening discourses at the Royal Institution by which Faraday encouraged the popularization of science, panicked at the last minute and ran out, leaving Faraday with a packed lecture hall and no lecturer. On the spur of the moment, Faraday offered "Thoughts on Ray Vibrations." Specifically referring to point atoms and their infinite fields of force, he suggested that the lines of electric and magnetic force associated with these atoms might, in fact, serve as the medium by which light waves were propagated. Many years later, Maxwell was to build his electromagnetic field theory upon this speculation.

When Faraday returned to active research in 1845, it was to tackle again a problem that had obsessed him for years, that of his hypothetical electrotonic state. He was still convinced that it must exist and that he simply had not yet discovered the means for detecting it. Once again he tried to find signs of intermolecular strain in substances through which electrical lines of force passed, but again with no success. It was at this time that a young Scot, William Thomson (later Lord Kelvin), wrote Faraday that he had studied Faraday's papers on electricity and magnetism and that he, too, was convinced that some kind of strain must exist. He suggested that Faraday experiment with magnetic lines of force, since these could be produced at much greater strengths than could electrostatic ones.

Faraday took the suggestion, passed a beam of plane-polarized light through the optical glass of high refractive index that he had developed in the 1820s, and then turned on an electromagnet so that its lines of force ran parallel to the light ray. This time he was rewarded with success. The plane of polarization was rotated, indicating a strain in the molecules of the glass. But, once again, Faraday noted an unexpected result. When he changed the direction of the ray of light, the rotation remained in the same direction, a fact that Faraday correctly interpreted as meaning that the strain was not, after all, in the molecules of the glass but in the magnetic lines of force. The direction of rotation of the plane of polarization depended solely upon the polarity of the lines of force; the glass served merely to detect the effect.

Discovery of diamagnetism

This discovery confirmed Faraday's faith in the unity of forces, and he plunged onward, certain that all matter must exhibit some response to a magnetic field. To his surprise he found that this was in fact so, but in a peculiar way. Some substances, such as iron, nickel, cobalt, and oxygen, lined up in a magnetic field so that the long axes of their crystalline or molecular structures were parallel to the lines of force; others lined up perpendicular to the lines of force. Substances of the first class moved toward more intense magnetic fields; those of the second moved toward regions of less magnetic force. Faraday named the first group paramagnetics and the second diamagnetics. After further research he concluded that paramagnetics were bodies that conducted magnetic lines of force better than did the surrounding medium, whereas diamagnetics conducted them less well. By 1850 Faraday had evolved a radically new view of space and force. Space was not "nothing," the mere location of bodies and forces, but a medium capable of supporting the strains of electric and magnetic forces. The energies of the world were not localized in the particles from which these forces arose but rather were to be found in the space surrounding them. Thus was born field theory. As Maxwell later freely admitted, the basic ideas for his mathematical theory of electrical and magnetic fields came from Faraday; his contribution was to mathematize those ideas in the form of his classical field equations.

From about 1855, Faraday's mind began to fail. He still did occasional experiments, one of which involved attempting to find an electrical effect of raising a heavy weight, since he felt that gravity, like magnetism, must be convertible into some other force, most likely electrical. This time he was disappointed in his expectations, and the Royal Society refused to publish his negative results. More and more, Faraday began to sink into senility. Queen Victoria rewarded his lifetime of devotion to science by granting him the use of a house at Hampton Court and even offered him the honour of a knighthood. Faraday gratefully accepted the cottage but rejected the knighthood; he would, he said, remain plain Mr. Faraday to the end. He died on August 25, 1867, and was buried in Highgate Cemetery, London, leaving as his monument a new conception of physical reality.

BIBLIOGRAPHY. An exhaustive account of Faraday's life and work is L. PEARCE WILLIAMS, *Michael Faraday* (1965, reissued 1971). Faraday's ideas on field theory and their later development by Maxwell are treated in L. PEARCE WILLIAMS, *The Origins of Field Theory* (1967, reissued 1981). Earlier biographies still worth consulting are JOHN TYNDALL, *Faraday As a Discoverer* (1869, reissued 1961); and SILVANUS P. THOMPSON, *Michael Faraday: His Life and Work* (1898). JOSEPH AGASSI, *Faraday As a Natural Philosopher* (1971), described as a historical novel, is interesting but untrustworthy as an account of Faraday's life and thought. Faraday's ideas can be found in his *Experimental Researches in Electricity*, 3 vol. (1839–55; reissued in 2 vol., 1965). *The Selected Correspondence of Michael Faraday*, ed. by L. PEARCE WILLIAMS, 2 vol. (1971), follows Faraday's ideas and discourses with colleagues on a host of subjects.

Farming and Agricultural Technology

In spite of the often concentrated industrialization of many parts of the world, the ancient calling of agriculture continues to draft into its service more of the world's aggregate manpower than all other occupations combined. Farming can be described as the art of making land more productive, and agricultural technology can be described as the application of techniques to control the growth and harvesting of animal and vegetable products. This technology has a long history, dating back to the beginnings of the human race. While farming is still practiced in some areas by methods not far removed from the conditions of several thousand years ago, this article is concerned with relatively modern techniques, discussing modern agriculture as a practical art, a commercial enterprise, and a science.

Historical aspects of farming technologies described in this article are covered in the articles AGRICULTURE, THE HISTORY OF; and TECHNOLOGY, THE HISTORY OF. The academic disciplines that study, develop, and teach scientific techniques of farming are discussed in AGRICULTURAL SCIENCES. The processing and distribution of agricultural commodities are treated in FOOD PROCESSING and BEVERAGE PRODUCTION. FORESTRY AND WOOD PRODUCTION and GARDENING AND HORTICULTURE cover sciences that are closely related to farming, and the manufacture of synthetic fertilizers is covered in INDUSTRIES, CHEMICAL PROCESS. The changing role of agriculture in developing countries is taken up in ECONOMIC GROWTH AND PLANNING and LAND REFORM AND TENURE. For information on farming and agricultural technology in specific countries or regions, see articles such as CHINA; AFRICA; or UNITED STATES: *Wisconsin.*

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 533 and 731, and the *Index.* (Ed.)

This article is divided into the following sections:

AGRICULTURAL ECONOMICS

Agriculture is the source of livelihood for more than half of the world's population. In some countries more than four-fifths of the inhabitants support themselves by farming, while in the more industrialized countries the proportion ranges much lower—to less than 3 percent in both the United States and Great Britain. In general one can say that, when a large fraction of a nation's population depends on agriculture for its livelihood, average incomes are low. This does not mean that a nation is poor because most of its population is engaged in agriculture; it is closer to the truth to say that because a country is poor most of its people must rely upon agriculture for a living.

Agriculture and economic development

The rural surplus

As a country develops economically, the relative importance of agriculture declines. The primary reason for this was shown by the 19th-century German statistician Ernst Engel, who discovered that as incomes increase the proportion of income spent on food declines. For example, if a family's income were to increase by 100 percent, the amount it would spend on food might increase by 60 percent; if formerly its expenditures on food had been 50 percent of its budget, after the increase they would amount to only 40 percent of its budget. It follows from this that, as incomes increase, a smaller fraction of the total resources of society is required to produce the amount of food demanded by the population.

PROGRESS IN FARMING

This fact would have surprised most economists of the early 19th century, who feared that the limited supply of land in the populated areas of Europe would determine that continent's ability to feed its growing population. Their fear was based on the so-called law of diminishing returns: that under given conditions an increase in the amount of labour and capital applied to a fixed amount of land results in a less than proportional increase in the output of food. This principle is a valid one, but what the classical economists could not foresee was the extent to which the state of the arts and the methods of production would change. Some of the changes occurred in agriculture; others occurred in other sectors of the economy but had a major effect on the supply of food.

In looking back upon the history of the more developed countries, one can see that agriculture has played an important part in the process of their enrichment. For one thing, if development is to occur, agriculture must be able to produce a surplus of food to maintain the growing nonagricultural labour force. Since food is more essential for life than are the services provided by merchants or bankers or factories, an economy cannot shift to such activities unless food is available for barter or sale in sufficient quantities to support those engaged in them. Unless food can be obtained through international trade, a country does not normally develop industrially until its farm areas can supply its towns with food in exchange for the products of their factories.

Economic development also requires a growing labour force. In an agricultural country most of the workers needed must come from the rural population. Thus agriculture must not only supply a surplus of food for the towns, but it must also be able to produce the increased amount of food with a relatively smaller labour force. It may do so by substituting animal power for human power or by gradually introducing labour-saving machinery.

Agriculture may also be a source of the capital needed for industrial development to the extent that it provides a surplus that may be converted into the funds needed to purchase industrial equipment or to build roads and provide public services.

For these reasons a country seeking to develop its economy may be well advised to give a significant priority to agriculture. Experience in the developing countries has shown that agriculture can be made much more productive with the proper investment in irrigation systems, research, fertilizers, insecticides, and herbicides.

Fortunately, many advances in applied science do not require massive amounts of capital, although it may be necessary to expand marketing and transportation facilities so that farm output can be brought to the entire population.

One difficulty in giving priority to agriculture is that most of the increase in farm output and most of the income gains are concentrated in certain regions rather than extending throughout the country. The remaining farmers are not able to produce more and actually suffer a disadvantage as farm prices decline. There is no easy answer to this problem, but developing countries need to be aware of it; economic progress is consistent with lingering backwardness, as can be seen in parts of southern Italy or in the Appalachian area of the United States.

PEASANT AGRICULTURE

One characteristic of undeveloped peasant agriculture is its self-sufficiency. Farm families in those circumstances consume a substantial part of what they produce. While some of their output may be sold in the market, their total production is generally not much larger than what is needed for the maintenance of the family. Not only is productivity per worker low under these conditions but yields per unit of land are also low. Even where the land was originally fertile, the fertility is likely to have been depleted by decades of continuous cropping. The available manures are not sufficient, and the farmers cannot afford to purchase them elsewhere.

Peasant agriculture is often said to be characterized by inertia. The peasant farmer is likely to be illiterate, suspicious of outsiders, and reluctant to try new methods; food patterns remain unchanged for decades or even centuries. Evidence, however, suggests that the apparent inertia may be simply the result of a lack of alternatives. If there is nothing better to change to, there is little point in changing. Moreover, the self-sufficient farmer is bound to want to minimize his risks; since a crop failure can mean starvation in many parts of the world, farmers have been reluctant to adopt new methods if doing so would expose them to greater risks of failure.

The increased use worldwide of high-yielding varieties of rice and wheat since the 1960s has shown that farmers are willing and able to adopt new crops and farming methods when their superiority is demonstrated. These high-yielding varieties, however, require increased outlays for fertilizer, as well as expanded facilities for storage and distribution, and many developing countries are unable to afford such expenditures.

THE LABOUR FORCE

As economic development proceeds, a large proportion of the farm labour force must shift from agriculture into other pursuits. This fundamental shift in the labour force is made possible, of course, by an enormous increase in output per worker as agriculture becomes modernized. This increase in output stems from various factors. Where land is plentiful the output per worker is likely to be higher because it is possible to employ more fertilizer and machinery per worker.

Land, output, and yields

Only a small fraction of the world's land area—about one-tenth—may be considered arable, if arable land is defined as land planted to crops. Less than one-fourth of the world's land area is in permanent meadows and pastures. The remainder is either in forests or is not being used for agricultural purposes.

GENERAL RELATIONSHIPS

Land and population

There are great differences in the amount of arable land per person in the various regions of the world. The greatest amount of arable land per capita is in Oceania; the least is in China. No direct relationship exists between the amount of arable land per capita and the level of income; Europe has almost as little arable land per capita as Asia and less than Africa; Japan and The Netherlands have very limited amounts of arable land per capita.

The relationship between land, population, and farm production is a complex one. In traditional agriculture, where methods of production have changed little over a long period of time, production is largely determined by the quality and quantity of land available and the number of people working on the land. Until the early years of the 20th century, most of the world's increase in crop production came either from an increase in land under cultivation or from an increase in the amount of labour used per unit of land. This generally involved a shift to crops that would yield more per unit of land and required more labour for their cultivation. Wheat, rye, and millet require less labour per unit of land and per unit of food output than do rice, potatoes, or corn (maize), but generally the latter yield more food per unit of land. Thus, as population density increased, the latter groups of crops tended to be substituted for the former. This did not hold true in Europe, where wheat, rye, and millet expanded at the expense of pasture land; but these crops yielded more food per acre than did the livestock that they displaced.

Impact of modernization

As agriculture becomes modernized, its dependence upon land as well as upon human labour decreases. Animal power and machinery are substituted for human labour; mechanical power then replaces animal power. The substitution of mechanical power for animal power also reduces the need for land. The increased use of fertilizer as modernization occurs also acts as a substitute for both land and labour; the same is true of herbicides and insecticides. By making it possible to produce more per unit of land and per hour of work, less land and labour are required for a given amount of output.

RECENT TRENDS

Crop yields have increased dramatically since 1950, with a faster rate of growth in the developing than in the developed countries. Most of this increased output has been due to gains in yields rather than to the expansion of cultivated land.

In Europe as well as in North and Central America, the total area under crops has declined; in South America it has increased by more than one-half and in Asia by more than one-third. The large increase in Oceania was due to immigration. The large decrease in Africa was due to a succession of droughts from the 1970s on.

Grain yields in the developed regions of the world have increased consistently over the past several decades. In the rest of the world the pre-World War II yields were not achieved again until the mid-1950s. The increases in grain production were more than twice as high in the developing as in the developed countries.

Food production and total agricultural production exhibit nearly identical trends, and changes in food production can be taken therefore as indicative of changes in total agricultural production. Food supplies per capita in developing countries have increased at nearly the same rate as in developed countries, indicating a narrowing gap between food supplies and population growth in the developing countries.

Efforts to control prices and production

The need for control

In the past few decades governments have undertaken to control both prices and output in the agricultural sector, largely in response to the pressures of the farmers themselves. In the absence of such control, farm prices tend to fluctuate more than do most other prices, and the incomes of farmers fluctuate to an even greater degree. Not only are incomes in agriculture unstable, but they also tend to be lower than incomes in other economic sectors.

THE PROBLEM

Instability of prices. The instability of farm prices results from several factors. One is the relative slowness with which farmers are able to respond to changes in the demand for their product. Farmers generally must produce on the basis of expectations, and if their expectations turn out to be wrong, the resulting surplus or shortage cannot be corrected until the beginning of the next production cycle. Once a crop is planted, very little can be done to increase or decrease production in response to market prices. As long as prices cover current operating costs, such as the cost of harvesting, it pays farmers to carry through their production plans even if prices fall to a very low level. It is not unusual for the prices of particular farm products to vary by a third or a half from year to year. This extreme variability results from the relatively low responsiveness of demand to changes in price—*i.e.*, from the fact that in order to increase sales by 5 percent it may be necessary to reduce the price by 15 percent.

Instability of income. The instability of farm prices is accompanied by instability of farm income. While gross income from agriculture generally does not vary as much as do individual farm prices, net income may vary more than prices. In modern agriculture costs tend to be relatively stable; the farmer is unable to compensate for a drop in prices by reducing his payments for machinery, fertilizer, or labour.

Relative stability of costs and its effect on income

The incomes of farm workers are generally below those of other workers. There are two major reasons for this inequity. One is that in most economies the need for farm labour is declining, and each year large numbers of farm people, especially young ones, must leave their homes to seek jobs elsewhere. The difference in returns to labour is required to bring about this transfer of workers out of farming; if the transfer did not occur, farm incomes would be even more depressed. The second major reason for the income differences is that farm people generally have less education than do nonfarm people and are able to earn less at nonfarm jobs. The difference in education is of long standing and is found in all countries, developed and undeveloped; it also exists whether the national education system is highly decentralized, as in the United States, or highly centralized, as in France.

GOVERNMENT INTERVENTION

Governments have employed various measures to maintain farm prices and incomes above what the market would otherwise have yielded. These have included tariffs or import levies, import quotas, export subsidies, direct payments to farmers, and limitations on production. Tariffs and import quotas can be effective only if a nation normally imports some of its supply. Export subsidies result in higher prices to domestic consumers than to foreign purchasers; their use requires control over imports to prevent foreign supplies from entering the domestic market and bringing prices down. Direct payments to farmers have been used to maintain prices to consumers at reasonable levels, while assuring farmers a return above world-market levels. Limitations on production, intended to reduce supply and thus increase prices, have been used mainly in Brazil (for coffee) and in the United States (for major crops).

The U.S. approach. Since the enactment of the Agricultural Adjustment Act of 1933, the United States has had programs designed to limit the production of major farm crops through restrictions on acreage. Since that date it has also offered price supports for major crops such as wheat, feed grains, rice, tobacco, peanuts (groundnuts), and cotton, as well as for manufactured dairy products. It has not had price-support programs for perishable crops or for major livestock products except for a few years during and after World War II.

The Commodity Credit Corporation

The price-support method most widely used has been the nonrecourse loan made by the Commodity Credit Corporation (CCC): the farmer may repay the loan by delivering his produce at the support price or "redeem" it in cash if the market price is higher. The amount of particular crops offered for price-support loans has varied greatly from year to year, as have redemptions.

Most of the farm products given price supports were crops normally exported by the United States. Until the mid-1960s the price supports were above the export prices. Unless export subsidies were paid to make up the difference between domestic prices and the prices foreign buyers were willing to pay, exports became impossible. Export subsidies were accordingly paid on such farm commodities as cotton and grains. In the 1960s the support prices for the major export commodities, except tobacco, were established at levels near or slightly below world prices to permit market forces to manage the distribution of supplies between domestic and foreign markets. The lowering of support prices was accompanied by a substantial increase in the size of direct payments to farmers. By the end of the 1960s such payments had come to constitute a high percentage of the cash receipts from farm marketings: in cotton, 60 percent; in wheat, 40 percent; and in feed grains, 30 percent. These payments fell sharply in the late 1970s, largely as a result of increased demand.

In order to receive payments, farmers had to agree to limit the acreage devoted to specified crops. At the beginning of the 1970s the various programs had resulted in the diversion of approximately 20,000,000 hectares of land from the production of major farm crops. The number of acres diverted from cultivation fell sharply, however, in the late 1970s and early 1980s.

A major component of U.S. farm price policy since World War II has been the disposal of surplus produce abroad through the economic aid program. This began as an outgrowth of wartime Lend-Lease, and food exported from the United States made a major contribution to the postwar recovery of western Europe. The Agricultural Trade and Development Act of 1954 provided a base for continuing such activities, and gradually the emphasis shifted from western Europe to the developing countries. One of the important effects was to dispose of farm products that could not be sold either domestically or in regular commercial foreign trade. Without this the farm income and price objectives could not have been achieved except by more stringent output limitations, lower farm prices, and larger direct government payments.

The British approach. Efforts to control agricultural prices go far back in English history, although the early objectives were quite different from those of more recent times. The Corn Laws of the 15th century were designed to prevent prices from becoming too high; restrictions were imposed on the right to export corn (wheat) when the domestic price exceeded a specified level. In 1663 the laws were revised to prevent prices from falling too low, by including import duties when the home price did not exceed a specified level. The general trend, until the Corn Laws were finally abandoned in 1846, was increasingly toward ensuring higher prices for home producers through the payment of export bounties and by the restriction of imports until prices reached specified levels. After 1846 the British followed a free-trade policy for agricultural products but moved to the protection of agriculture and the establishment of minimum prices for certain farm products during the depression of the 1930s. Protection was expanded after World War II by legislation in 1947 and 1957 which sought to support farm prices primarily through deficiency payments to farmers, covering about 95 percent of total output. In most cases the domestic price was free to vary with changing demand and supply conditions; local products competed with imported supplies that were generally subject to relatively low tariffs. The farmer was reimbursed for the difference between his average realized price and a guaranteed price. The Agricultural Act of 1957, which gave the government the right to limit the amount of agricultural output on which deficiency payments were made, was designed to reduce the cost of the program and to encourage domestic production.

The British system of supporting farm prices, while allowing consumers the lowest possible food prices in the world market, was gradually abandoned during the late 1960s as the United Kingdom prepared for entry into the European Economic Community (EEC). When the United Kingdom entered the EEC in 1972, its agricultural prices began to rise to the much higher level prevailing within the EEC. The United Kingdom, moreover, imports more food and live animals from EEC countries than it exports, leading many British to question the value of membership in the EEC.

Policies of the EEC. The EEC has established a common agricultural policy (CAP) for the Common Market countries. The CAP, worked out for each major farm commodity, was originally designed to create free trade for that commodity within the community. Special subsidies by the individual countries, and other national farm programs, were to be eliminated to prevent competitive advantages. The first of the regulations implementing the CAP were enacted in 1962 and applied to grain (except rice), poultry, eggs, live hogs and whole hog carcasses, fruit and vegetables, and wine. Similar programs were developed later for beef, dairy products, sugar, rice, and fats and oils.

The regional approach

The most important features of the CAP mechanism are the target prices, the threshold prices, the support or intervention prices, the variable levies on imports to make up the difference between landed prices and threshold prices, and export subsidies or refunds equal to the difference between market prices in the EEC and in the importing country. For most CAP commodities the primary device for achieving target prices is the variable import levy. This levy, which fluctuates with the import cost of a commodity, keeps the domestic price at or near the target price if the commodity is imported. When EEC production of a commodity exceeds EEC consumption, the authorities may purchase the commodity for storage, pay to have it processed for another use (*e.g.*, wheat may be denatured and sold as a feed grain), or subsidize its export to countries outside the EEC. With these techniques the EEC has been able to maintain farm prices at levels substantially higher than those prevailing in the United States and Canada.

Throughout the 1960s the EEC did nothing to limit or control the production of agricultural products. When large stocks of butter and dry skim milk accumulated, and as the costs of maintaining dairy product prices and subsidizing wheat exports mounted, consideration was given to reducing production. A payments program to induce shifts from dairy to beef production was inaugurated, and there was talk of reducing the area cultivated for grain. Output limitation has been made difficult, however, by the significant differences in circumstances among the farmers in the various EEC countries.

The centralized approach

Soviet policies. The farm policies of the Soviet Union were established during the First Five-Year Plan (1928–32), when agriculture was collectivized. For all practical purposes, regular markets for farm products were abolished at that time, and each collective farm was required to deliver an assigned quota of produce to the state at very low prices. If a farm had anything left after meeting the obligatory quotas, it could sell the surplus to the state at higher prices or to the local free markets. Until 1958 the collective farms also had to make payments in kind to the machine tractor stations in return for work done.

After Stalin's death in 1953, farm prices were increased significantly; the average procurement prices for food products increased almost fourfold between 1950 and 1956. In 1958 the multiple-price system was abandoned, and the prices paid to collective farmers became almost seven times the average paid in 1950. The machine tractor stations were abolished in 1958 and the machinery transferred to individual farms. Another major revision of prices was made by the post-Khrushchev government in 1964–65. A two-price system replaced the single prices; prices for deliveries of grain up to the planned amount were about 10 percent higher than the previous single price, and deliveries above the plan level received a premium of 50 percent. Significant regional price differentials were established to cover the higher costs of production in some regions. Prices of livestock products had already been increased by about 35 percent in 1962, and in 1965 further increases of perhaps a third were made. Another important measure was a commitment that planned purchases were to be fixed at specified levels during the Eighth Five-Year Plan (1966–70), both in the aggregate and for individual farms. Prior to that time, if a farm had significantly increased its production or if other farms in the same region had failed to meet their deliveries, the delivery quota might be arbitrarily increased for the farm that happened to have had some output available for delivery.

Soviet price policy before 1953 was clearly designed to obtain farm products as cheaply as possible. The low prices were generally not passed on to consumers; a significant fraction of total governmental revenue was derived from high taxes on farm products. The changes made after 1953 were intended to provide farmers with an incentive to raise production and to make more efficient use of resources. Only a part of the increase in prices paid to farms was passed on to consumers; much of the increase was at the expense of government revenue.

In the late 20th century Soviet planning began to give greater emphasis to private plots; while constituting only about 1.5 percent of Soviet farmland, these plots produced about one-third of the nation's agricultural output other than grains. Restrictions on the crops private plots could produce were relaxed, and the importance of those plots was stressed. State farms and collectives, however, continued to receive the vast majority of capital and feed grains. Private plots, moreover, suffered from many of the problems that stunted the state farms and collectives, including the flight of young people from the countryside.

THE PROBLEM OF STANDARDS

None of the governments engaged in regulating farm prices and incomes has been able to apply a meaningful standard as to what a fair price or reasonable income is. The actual measures adopted, such as specific price supports or intervention prices, have been determined through the political process, with little reference to formal principles or standards.

Governmental attempts to regulate prices and incomes

In the United States the Agricultural Adjustment Act of 1933 stated that the goal should be to establish prices having the same purchasing power as those of the period 1910–14. By the end of World War II it had become clear that the "parity price" relationships of 1910–14 were no longer relevant to existing conditions. The Agricultural Act of 1948 retained the 1910–14 average as a parity for all farm products but stated that the parity for individual products was to be the average of prices over the most recent 10-year period. Since the application of this formula would have resulted in a significant reduction in the parity prices for some politically important farm products, particularly cotton and wheat, legislation that was passed in 1949 declared that the parity price for an individual commodity was to be determined by either the old or the new formula, whichever was higher. Not until 1955 were the "modernized parity" prices put into effect on a gradual basis. The Food and Agricultural Act of 1977 introduced cost of production as a standard for determining farm price supports. This standard, however, is far from absolute, since the cost of production varies from one region to another; moreover, many costs of production, such as rent, are influenced by the value of the crops produced.

There has been a similar lack of objective or measurable standards in other countries. In Great Britain, for example, the Agriculture Act of 1947 declared its intention to be that of

> promoting and maintaining a stable and efficient agricultural industry capable of producing such part of the nation's food and other agricultural produce as in the national interest it is desirable to produce in the United Kingdom, and of producing it at minimum prices consistently with proper remuneration and living conditions for farmers and workers in agriculture and an adequate return on capital invested in the industry.

Several other countries have legislation that aims, without specifying in practice what is meant, to obtain for farm people the same level of income as that of other groups in the economy or that states that farm people should share in the rise in real per capita incomes. Finland, Japan, France, Sweden, and Norway have such policy objectives. German legislation declares that agriculture should share in the progressive development of society and requires that the government each year prepare a report showing the extent to which the return to farm labour, or properly managed holdings under average conditions, is in line with that of wage earners in comparable nonagricultural occupations in rural areas.

The agricultural price objectives of the Treaty of Rome, which established the EEC, also lack practical significance:

> To ensure . . . a fair standard of living for the agricultural population, particularly by the increasing of the individual earnings of persons engaged in agriculture; to stabilize markets; to guarantee regular supplies; and to ensure reasonable prices in supplies to consumers.

ACCOMPLISHMENTS

The effects of price and income policies are difficult to assess. The policies have unquestionably worked to raise agricultural production in the countries where they have been applied, but their usefulness as a means of enhancing the economic well-being of farm people is debatable. The governments of the industrial countries have been able to raise the returns from agriculture above the levels that would have prevailed in the absence of such intervention. In addition to maintaining prices, they provide subsidies for agricultural inputs such as tractor fuel and chemical fertilizers; they also gave assistance in consolidating small farms into larger ones and in improving farm buildings. They do not, except for the United States, attempt to moderate the effects of these policies on production.

Factors affecting income level and economic well-being

The level of income and the economic well-being of farm people in general are determined by many factors, including not only the prices they receive for their output but also the rate at which the economy in general is growing, the ease with which people can move from farm to nonfarm jobs, the prices they must pay for their productive inputs, and their level of education. With respect to average income per person, as distinguished from total income, the prices received and paid are probably less important than the other factors mentioned. This becomes obvious when one compares farm incomes in the United States or the United Kingdom with those in Argentina or India; the differences in real income have to do mainly with the levels of economic development and not with farm prices or subsidies. Government efforts to increase farm prices are likely to be offset, in the long run, by an increase in the number of persons engaged in farming, and this tends to keep the returns to farm labour from rising much faster than they would in the absence of such policies.

There are two other reasons for believing that the income effects of higher farm prices or subsidies are relatively insignificant in the long run compared with other factors affecting incomes of farm workers. One is that an increase in farm prices induces farmers to use more fertilizer, machinery, fuel and oil, and other items. If a significant part of any increase in gross income is used for such things, the absolute increase in net farm income is much smaller than the increase in gross farm income. The second reason is that a given increase in government-supported farm prices generally occurs only once. After the increase in returns has been realized, the higher farm prices contribute nothing further to incomes. In contrast, general economic growth along with the continued reduction of the farm labour force has cumulative effects on the return to farm labour. If the returns to farm labour were to grow at an average annual rate of about 3 percent, for example, farm prices would have to increase at least 3 percent annually (assuming other prices did not change) to have the same effect on returns to farm resources.

COSTS

The costs of the agricultural price and income policies of industrial countries are substantial; they include not only direct governmental outlays but also the increased costs to consumers in those countries, as well as the losses to developing countries of potential export markets.

The high prices of farm products in the United States in the mid-1970s and the relaxation of interventionist policies by the EEC after 1974 substantially reduced the costs of farm programs in these two regions. With the decline of farm prices that began in 1976, costs to taxpayers and consumers again approached the levels of the early 1970s.

The organization of farming

OWNERSHIP

Except in nations with Communist governments, most farm land is privately owned. This does not mean, however, that the land is owned by those who farm it. In most countries a major aspiration of farm people has been to achieve the ownership of the land they work. After World War II, Japan and Taiwan underwent land reforms that were intended to broaden ownership; these are generally considered to have been highly successful. Similar reforms have been advocated in other countries.

The variety of forms of ownership and operation

On a cooperative farm the land is owned jointly by the members of the group who farm it. The cooperative generally also owns all the major means of production, and the members supply all or most of the labour. While there are examples of cooperative farms in many countries, they loom large only in Israel, where the kibbutzim control about a fifth of the total agricultural land.

In a collective farm, at least as organized in the former Soviet republics, the land was owned by the state but was permanently leased to the *kolkhoz* (collective farm). The *kolkhoz* owned its own equipment and livestock and was required to meet certain commitments to the state in the form of deliveries of farm products. In theory the members of the *kolkhoz* were to elect the officers of the farm and establish the procedures by which the net product was to be divided among the members for services performed. In practice, however, their autonomy was severely limited by the economic plans. In most cases these plans were incredibly detailed, specifying the crops to be grown, the times of plowing, planting, and harvesting, the quantities of fertilizer and manures to be used, and the kinds of livestock to be maintained.

On state farms the land and all other means of production are owned by the state. The workers are paid in wages, and management decisions are made by individuals directly responsible to the state.

KINDS OF FARM OPERATION

If a family farm is defined as one for which the farm operator and members of his family supply at least half of the labour, the majority of farms in the world are family farms. Family farming is carried on under a wide range of conditions, from the small farms of Asia to the highly mechanized farms of Canada, the United States, and the United Kingdom.

The family farm may be owned by the farmer or rented. The most rapidly expanding type of tenure in the United States is that in which the farmer owns part of the land and rents the remainder; almost one-third of all farmland in the United States consists of part-owner farms. This arrangement enables the farmer to increase the size of the farm through renting and to invest capital in machinery and livestock.

Family farms may be large in terms of total assets or sales. The relative importance of family farms among the largest farms in the United States has increased over the past few decades. One of the more striking changes in industrial countries has been the increased importance of nonfarm income received by farm families. In the United States, Canada, and Japan more than half of the total income of farm families comes from nonfarm sources, while in most western European countries at least a third of the income of farm families is earned outside of agriculture.

A system of tenant farming known as sharecropping developed in the South of the United States following the freeing of the slaves in the 19th century. It was essentially an adjustment of the plantation system created to permit the owners to maintain a large measure of control over farm operations. The sharecropper usually supplied only the labour, while the owner provided animal power, machinery, and most of the other inputs in the form of an advance. The sharecropper received what was left after he had paid back the owner—generally about half of what had been produced.

For various reasons, including the exodus of blacks from American agriculture, the introduction of farm machinery, and the reduction in the acreage of cotton, the number of sharecroppers in the South has diminished by well over 80 percent since 1935.

In the past several decades there has been a growth of large-scale farming run as a business enterprise. These "industrial farms" are of growing significance in world agriculture. There are farms covering extensive areas of land in Africa, South America, and Australia, but most of them do not rely heavily upon machinery or other purchased inputs. Farms in the United States are becoming larger as their numbers grow smaller. Such large farms tend to specialize in the production of vegetables, fruits, cotton, poultry and poultry products, and livestock.

COMPARATIVE STRENGTHS AND WEAKNESSES

If they were free to choose, most farm families would want to own the land they farm. Wherever collectivization of private farmers has been carried out, it has required the use of force or the threat of force. But if family farming is to be viable, it must function efficiently, which means that farmers must have access to adequate sources of credit; must be able to obtain fertilizers, machinery, and other equipment; and must be able to market their produce easily. Laws and institutions must be sufficiently flexible to permit the average size of farms to increase as economic growth occurs.

Collective farming did not fulfill the hopes of its early advocates. In the Soviet Union the collective farm was used by Stalin as a means of exploiting the rural population in order to finance the expansion of industrialization. In the post-Stalin era the incomes of collective farm members increased, and it was believed that many remaining difficulties could be eliminated if the farms were given greater freedom in running their affairs. Nothing in the concept of the collective farm required the imposition of delivery quotas, centralized control of farm investment, or a particular organization of farm labour. Another weakness of collective farms was the failure to provide adequate incentives for individual members. Because of the difficulties involved in rewarding members for their individual work on the common land, the household plots of the members all too often tended to flourish at the expense of the collective.

There is no ideal form of organization that fits all farming. Under some circumstances the ownership of land may absorb so much capital that other investments, such as machinery and livestock, are neglected. Land rental may be a better alternative for many families, especially those with limited capital. The Israeli kibbutz has made it possible for many people with little or no agricultural experience to learn farming techniques quickly and efficiently. The most important consideration is whether the other institutions—economic, political, and social—are adequate to provide farmers with a wide range of resources and alternatives. (D.G.J./Ed.)

THE BASIC UNIT OF OPERATION: THE FARM

Farm buildings

The basic unit of commercial agricultural operation, throughout history and worldwide, is the farm. Because farming systems differ widely, there are important variations in the nature and arrangements of farm facilities. The buildings on a farm generally consist of the farm family's house, the dwellings of any resident hired workers, and the various structures and facilities for farming operations. This section deals with farmhouses and service buildings that can be classified as follows: livestock barns and shelters; machinery- and supply-storage buildings; buildings and facilities for crop storage, including fodder; and special-purpose structures.

GENERAL LAYOUT

The location of the farmstead and the relative position of its different buildings are influenced by several factors, external and internal. Among the external factors, mainly natural, are soil conditions, climatic conditions, and access facilities to the main road and to the fields.

Internal factors depend on the type of business enterprise suitable to the farm. Among general principles that must be taken into account are the necessity of some partition between the farmhouse and service buildings, minimizing of transportation between buildings, the possibility of enlarging buildings, and security against fire. Four general layouts may be defined: large crop farms, large stock farms, farms in underdeveloped areas, and small to medium mixed farms.

Large crop farms. Independently owned farms of this type, mainly cash-grain farms, are numerous in North America. The layout is simple: there are generally two types of service buildings, one for storage and the other for machinery. Large farms specializing in fruit production have a shed for the conditioning and storing of products, the other main building being a machinery and supply shelter. Some large farms specializing in viticulture include buildings that are equipped with wine cellars.

Extensive and intensive stock farm types

Large stock farms. Two types of large stock farms, extensive and intensive, may be distinguished. The extensive type is exemplified by the cattle ranchers of the United States. At the extreme, there are no buildings, only equipment. In Australia and New Zealand, dairy cows are kept without housing. The only building houses the milking parlour and the milk room, in the centre of the pasture. In the western United States, the most important beef ranches have several thousand head, entirely free on the range. The only building is the elevator with the milling and mixing machinery. For the animals there are only troughs and fences. Among intensive stock farms are the big dairy units—with several hundred cows—in the United States, in western Europe (France, northern Italy), and in eastern Europe and the former Soviet republics. There are three major layouts: parallel buildings; monobloc buildings (in Hungary, for example); and circular layout, with the milking parlour in the centre (United States, northern Italy). The covered feedlots for fattening beef, in the U.S. Midwest and elsewhere, feed from several hundred to several thousand head of cattle and are generally built with a shelter for the animals and with tower or bunker silos. Large units for hog production frequently have many buildings, partly to reduce disease risks and partly to separate the various animals—for example, the suckling sows, in-pig sows, fattening pigs, and boars. Some systems, however, use only one or two types of buildings. Large poultry units, specialized either for egg or for broiler production, use large identical buildings, the number depending on the unit size.

Farms in underdeveloped areas. In the underdeveloped areas, two types of buildings are found: those of the latifundia, or large plantation-type farms, and those of the small-owner or tenant farms. In these, buildings are generally small and scattered, the construction of a single large building being too expensive.

Mixed farms. The small and medium farms, which characterize European agriculture and which exist in many other parts of the world, are managed on the traditional mixed-farming and animal-husbandry system. Consequently, this type of farm normally has several service buildings: one for machinery, one for hay and cattle, another for hogs, and still another for sheep. In mountain areas, however, there frequently is a single building, including the house. With the increase of the average size of farms in these areas, there is relative specialization, and the number of buildings in the newly built farms is decreasing.

BUILDING TYPES

These include homes (farmhouses), livestock barns and shelters, buildings for machinery and supplies, and crop-storage and special-purpose structures.

Farmhouses. The basic requirements for the farmer's family are about the same as those of the urban family, but certain features of the farmhouse depend on the farm-life pattern. Because the farmer generally comes directly from the fields or the service buildings, with soiled clothes and boots, it is necessary to provide a rear entrance with a washroom or lavatory and clothes-storage space. For the same reason, many farmers prefer a dining place close to the kitchen or included in it. The house must include an office and a large food-storage place with ample refrigeration, including a freezer in many countries, as most farm families are large. There are usually three or four bedrooms.

Satisfactory modernization of old farmhouses is difficult in some cases, but if the available floor space is sufficient and the main walls strong, renovation can give good results. The cost of a new house must be proportionate to the farmer's income; for this reason, farmhouses in underdeveloped regions have less floor space with a main room (kitchen and dining room), two or three bedrooms, a large washroom, and a storage place.

Livestock barns and shelters. These tend to become the most important elements of the farm layout. Two general types of animal shelters may be distinguished: the multipurpose type, a single-story building with clear-span roof construction, useful for feed storage and machinery, as well as for livestock; and the specific type, designed for a particular type of animal.

Types of cattle housing

There are two major cattle-housing methods, the stall barn (or stanchion barn) and the loose-housing system. In the stall barn each animal is tied up in a stall for resting, feeding, milking, and watering. The typical plan has two rows of stalls. In older buildings hay and straw are stored in an overhead loft, but in modern layouts adjacent buildings are generally used.

In cold and moderate climates the barns need insulated walls and ceilings, as well as ventilation systems, either natural or power-operated. In mild and hot areas the barns are open on one or two sides. The loose-housing system, developed in the United States after World War II, is now employed throughout the world. Basically, this system includes a wood- or metal-framed shelter, arranged in such a way that the animals can move freely inside and sometimes also between the shelter and an outside yard. Depending on the bedded areas, four types can be distinguished: loose housing on permanent litter—for example, straw, corncob, sawdust; loose housing in free stalls or cubicles; loose housing on slatted floors; and loose housing on sloped concrete.

In some countries, in old as well as in new buildings, dairy cows are housed in stall barns that include milk rooms. Milking takes place in stalls, and the milk is carried either in cans or directly by pipeline to a refrigerated tank in the milk room. Modern layouts with loose housing always include a milking parlour, either stationary or rotary. Two types of loose housing are used: loose housing on permanent litter and loose housing in free stalls, either under a clear-span roof or under a narrow lean-to roof. Beef-breeding cows often live on pastures, with only open-front sheds, during the calving period. In France and Scotland, however, they are kept in barns all winter. For fattening steers there are two major housing systems. The first of these is the American system, with very large groups of animals and a wide surface per animal. In the western United States the open feedlots include only fences, troughs, and alleys for feed distribution. In the Midwest Corn Belt a shelter is often included. The second, the European system, is characterized by very small groups (10 to 20 animals each) and a very small surface, generally covered. Any of the four loose-housing systems can be used.

For horses and ponies it is customary to use individual stalls, where the animal can move freely, even though this requires more space. Mules may be kept together in large pens. In mild climates sheep and goats live on pastures without any shelter. The facilities include fences, waterers, corrals, dipping vats, and lambing and shearing sheds. In moderate and cold climates the flock is wintered in sheds. The trend is toward clear-span buildings, with large alleys so that trailers can distribute feed into racks and troughs. Ewes are housed by groups (50 to 100 each), and special pens are kept for lambs. Feed racks and fence partitions are generally movable. For the dairy ewes there are special milking parlours. Goats are housed either in tie stalls, for small flocks under 50 head, with milking on the spot, or in pens, for larger flocks housed by groups, with milking in a special milking parlour. Pig housing varies for sows and fattening pigs. The sow lives with its litter for four to eight weeks according to the weaning age chosen. During this period there are two types of housing: movable, individual houses (generally of wood) located on or close to pastures and fixed in place, and central farrowing houses. A sow may farrow and live with its piglets in a single pen or farrow in a special stall, to avoid possibly crushing the piglets, or may farrow tied up by a chain or a harness. The pregnant sows live either free in groups of six to 12 or tied up or blocked up inside individual stalls. In cold climates the house is heated; in all modern practice infrared lamps or tubes are used to keep the piglets warm.

Fattening pigs, like fattening beef cattle, may be kept either in a simple feedlot, in large groups with a wide surface per head and a simple open shelter, a system widely used in the United States Corn Belt, or penned in a closed building, isolated and ventilated, each pen holding seven to 15 pigs. This is the most common system in Europe. Size of the pig units varies all the way from five sows or 20 pigs to large farms of up to 100,000 pigs. Poultry is the most industrialized type of animal production. Some of the breeding phases no longer take place in farms but in specialized plants; the farmer buys either chicks for broiler production or young layers for egg production. The typical modern broiler house holds from 10 to 100,000 birds, with automated feeding. Two types of facilities can be used. The broilers can be put on the ground on a deep litter of wood shavings, on wire mesh above a pit, or on a combination of these two floors. Alternatively, the broilers can be housed in metal cages, on three stories, each cage holding three to 10 animals. In this case, feeding and cleaning are mechanized and the density is higher. The typical laying house holds several thousand hens. The same facilities as for broilers are used, but use of the cage is more common for layers. There are several types of cages, some of which are mechanized to facilitate feeding, cleaning, and egg collecting. Each cage can hold one to five hens. The density can reach about 2 hens per square foot (23 hens per square metre). The main types are cages in two- or three-story batteries (California cages), which are not superposed but rise in tiers; and flat-deck cages, which allow maximum mechanization. The buildings are generally one story, fully enclosed; they have insulated structures with sophisticated ventilation systems. Turkeys and other fowl are housed like poultry but generally on the ground. Rabbit production involves housing by groups in cages, on one, two, or three stories.

Modern broiler houses

Buildings for machinery and supplies. This type of building is designed solely to afford protection from the weather, mainly rain. Machinery storage should have as much surface as possible between the interior posts, without being too deep, so that each machine can be taken out easily. The best solution is a clear-span shed, wood or metal-framed, 25 to 35 feet (eight to 10 metres wide), open on one side and 15 feet (4.5 metres) high under the gutter. At the end of the shed, one bay is reserved for repair and maintenance and another for tools. This part is equipped with sliding or overhead doors. The same shed, or another, can be used for storing the fertilizers, seeds, and pesticides.

Crop storage. Wheat, barley, shelled corn (maize), and other cereals can be stored in farm bins if the moisture is below a certain limit (from 10 to 15 percent). In some cases artificial drying is necessary before storage, though it is possible to store wet grain, especially shelled corn, in airtight silos for animal fodder. The most common methods of storage of dry grain are (1) in piles of five to 10 feet (1.5 to three metres) on a waterproof floor in a building with reinforced walls; (2) in square or round bins erected within a building, usually of timber, plywood, corrugated steel, or wire mesh lined with waterproof paper; and (3) in watertight bins, often of corrugated metal, with their own roofs, for outside erection. Ear corn is dried by natural ventilation through a crib of limited width, located in a building or outside. Loose or baled hay is stored and sometimes dried by ventilation with fresh or heated air, either under sheds or in special installations called hay towers. Silage is made to conserve moist fodders, such as corn, sorghum, and grass. There are two types of silos. The horizontal silo is a parallelepiped, either cut into the ground (trench silo) or built above ground (bunker silo). The floor is natural earth or concrete. The walls can be concrete, timber or plywood, or sheet steel. The capacity varies but can be large. The tower silo is an above ground cylinder, with 20- to 30-foot (six- to nine-metre) diameter and a 50- to 65-foot (15- to 20-metre) height.

Silos

Ordinary silos, which are only watertight, are of wood, concrete, masonry staves or blocks, or steel. Special airtight silos with steel walls and a fused-glass surface are used for storage of high dry-matter silage, called "haylage." Fruit and vegetable storage for family consumption is usually in caves or cellars. For crops to be marketed, conditioning and storage generally are handled by commercial enterprises, but some large, specialized farms have their own storage. The buildings are insulated, and temperature control is assured either by ventilation with outside air (*i.e.*, for potatoes and onions) or by refrigeration (*i.e.*, for apples).

Special-purpose structures. Many secondary farm structures, such as smokehouses and well houses, are a leftover of the past, but some are necessary in specialized farms. A typical example is the tobacco barn, built for static air circulation. (R.Ma./Ed.)

Farm management

Farm management normally consists of making and implementing the decisions involved in organizing and operating a farm for maximum production and profit. Farm management draws on agricultural economics for information on prices, markets, agricultural policy, and economic institutions such as leasing and credit. It also draws on plant and animal sciences for information on soils, seed, and fertilizer, on control of weeds, insects, and disease, and on rations and breeding; on agricultural engineering for information on farm buildings, machinery, irrigation, crop drying, drainage, and erosion control systems; and on psychology and sociology for information on human behaviour. In making his decisions, a farm manager thus integrates information from the biological, physical, and social sciences.

Because farms differ widely, the significant concern in farm management is the specific individual farm; the plan most satisfactory for one farm may be most unsatisfactory for another. Farm management problems range from those of the small, near-subsistence and family-operated farms to those of large-scale commercial farms where trained managers use the latest technological advances, and from farms administered by single proprietors to farms managed by the state.

The individual farm

In Southeast Asia the manager of the typical small farm with ample labour, limited capital, and only four to eight acres (1.6–3.2 hectares) of land, often fragmented and dispersed, faces an acute capital–land management problem. Use of early maturing crop varieties; efficient scheduling of the sequence of land preparation, planting, and harvesting; use of seedbeds and transplanting operations for intensive land use through multiple cropping; efficient use of irrigation and commercial fertilizer; and selection of chemicals to control insects, diseases, and weeds—all of these are possible measures for increasing production and income from each unit of land.

In western Europe the typical family farmer has less land than is economical with modern machinery, equipment, and levels of education and training, and so must select from the products of an emerging stream of technology the elements that promise improved crop and livestock yields at low cost; adjust his choice of products as relative prices and costs change; and acquire more land as farm labour is attracted by nonfarm employment opportunities and farm numbers decline.

On a typical 400-acre (160-hectare) corn-belt farm in the United States with a labour force equivalent to two full-time men, physical conditions and available technologies allow a wide range of options in farming systems. To reach a satisfactory income requires operating on an increasing scale of output and increasing specialization. Corn and soybean cash-crop farming systems have increased in number along with corn-hog-fattening farms and corn-beef-fattening farms. Thus, the choice of a farming system, the degree of specialization to be chosen, the size of operation, and the method of financing are top concerns of management.

For a typical crop-livestock farm in São Paulo's Paraíba Valley, Brazil, large-scale use of hired labour creates a substantial management problem. With 30 to 40 workers per establishment, procuring and managing the labour—keeping abreast of demand and supply conditions for hired labour, working out contractual arrangements (wage rates and other incentives), deciding how to combine labour with other inputs, and supervising the work force—are of critical importance.

A rancher with thousands of acres, whether in the pampas of Argentina, the plains of Australia, or the prairies of the United States, is concerned about the rate of increase of the herd through births and purchases and herd composition—cows, calves, yearlings, steers, heifers. Risks from drought, winter storms, and price changes can be high. Weather, prospective yields, and the price outlook are the constant concern of competent and alert farm managers.

The collective farm

On a collective farm in the Soviet Union with 30,000 acres (12,000 hectares) and 400 workers, major management decisions are made by party–state representatives; the collective-farm chairman responds largely to their directives, though the farm manager is being given greater autonomy. Major management concerns are determining optimal size of the collective, improving labour incentives, increasing crop and livestock yields, and reducing unit costs—with emphasis on levels of fertilizer, on pesticide and herbicide use, and on conservation of soil and water in crop production.

Thus, the character of the world's agriculture is shaped as millions of farmers manage the resources under their control in ways to obtain as much satisfaction as possible from their decisions and actions, which are made in a large variety of settings in regard to human, capital, and land resource combinations; technological possibilities; and social and political arrangements. Future agricultural progress depends on improving the quality of management and the environment in which farmers make decisions and on helping them adjust their decisions to the changing environment. In the low-income agricultures of the world in the 1980s, expanded research, improved input supplies and transport facilities, enlarged market opportunities, and an otherwise encouraging environment promise to open up a much wider area for managerial choice and decision making.

BASIC CONCERNS

Land, livestock, and labour. A good farm manager is familiar with the legal description of the farm property for which he is responsible, location relative to other property, roads, markets, and sources of supply, the details of the field arrangement and farmstead layout, the farm's capital position or relation of debts to assets, and the resources of the farm, such as the capabilities of its soils. Such facts enable the manager to analyze and evaluate his resources and plan their use. To calculate profit potential, the farm manager estimates the yield expected from each acre or hectare of land and from each head of livestock. He then applies money prices to these quantities.

Calculating farm size

The size of a farm business, an indication of its profit-making potential, is measured by the total number of acres or hectares in the farm, acres or hectares planted to cash crops, productive man-work units (the number of workdays of labour required under average efficiency to care for crops and livestock), livestock units kept, capital invested, and total cash receipts. While total acreage is often used to describe farm size, it is not a very satisfactory measure since it does not specify how much land is hilly, stony, swampy, or otherwise unproductive. Total cropped land, total receipts, invested capital, or productive work units are better measures. Though livestock are counted by the head for the sake of comparison, for management purposes one cow is roughly equal in value to two calves, five hogs, 10 young pigs, seven sheep, 14 lambs, or 100 laying hens.

While the amount of land in a farm is more or less fixed, many farmers buy or rent additional acreage to increase their volume of output as a means of reducing unit costs. If such acreage is available within a reasonable distance, then land can often be profitably exploited. Other ways of increasing volume include bringing unimproved pasture and woodland into the cropping plan and shifting either to more intensive methods of cultivation or to more valuable crops. Before making major changes, the farm manager attempts to assure himself that the new crops will grow well and will find a market in his area. Almost all the governments of the world today have departments or ministries of agriculture which have been established for the purpose of advancing agricultural welfare by spreading technological information. Often these agencies perform extensive experimentation with new crop varieties, new cultivation techniques, and improved breeds of livestock, thus reducing the burden of risk upon the individual farm manager contemplating such changes. Considerable experimentation and research are also carried out by private agricultural supply firms that hope to improve their competitive position in the marketplace by developing a valuable new product.

In some of the developing countries, traditional patterns of land tenure and laws of inheritance may result in one farmer holding many quite small plots at some distance from each other. To reduce the resulting labour inefficiency and low productivity and to spur development of large-scale agriculture, governments in these countries have frequently legislated to permit or compel consolidation of such holdings (see LAND REFORM AND TENURE).

Productive and non-productive farm labour

Some kinds of farm work are directly productive, some are indirectly productive, and some are not productive at all. Work such as plowing, planting, cultivating, harvesting, feeding, and milking is directly productive. Maintenance of fences, buildings, and machinery, though often necessary, is not directly productive. Such work as trimming shrubbery and mowing lawns, unless it adds to the market value of the farm, is not considered productive. Similarly, capital can be highly productive, as in the case of livestock; indirectly productive (*e.g.,* tractors, buildings, and supplies); or unproductive, as a large, showy barn or house. Land, too, can be highly productive, moderately so, or waste. Analysis of farm records has shown that farmers often overequip their property, thus using buildings and machinery to less than full capacity. Generally speaking, small farmers have been shown to have a higher proportion of their total investment in buildings than in machinery. In the developing countries, where relatively large quantities of human labour and relatively small amounts of capital are employed, a rather different problem exists. In these areas, farm managers need large numbers of people to work the fields during planting and harvest and far smaller numbers to perform routine cultivation tasks. In consequence, these countries face a problem of underemployment of agricultural labour during much of the year.

Financial management and large-scale operation. The financial tools a farmer can use to analyze, plan, and control his business include financial statements, profit and loss statements, and cash-flow statements. A financial statement tells the amount of money invested in farm assets, outstanding debts, the owner's equity in the business, and the degree to which the farm is liquid and solvent. Liquidity is the ability to meet financial obligations on time, whereas solvency is the ability to pay all debts if the business is forced to discontinue. A profit and loss statement shows sources and amounts of income and operating expenses. Comparison of profit and loss statements over a period of years tells which resources have been most profitable and whether there has been an advance or decline in net income. A cash-flow statement shows the sources and uses of funds at given periods during the year. Such a statement provides a useful check on the accuracy of the farm's other business records.

For the traditional farmer, land and labour (his own and that of his family) are the major resources. Under favour-

Conditions favourable to large-scale operations

able conditions, the farmer has changed his role from labourer to operator-manager; much larger farm units with high capital investments have resulted. Such conditions include the existence of a considerable body of applicable scientific knowledge, an opportunity for greater efficiency from large-scale operations, the existence of good markets and transportation, the opportunity to routinize and centrally direct farm work, and an absence of community antagonism to large-scale agriculture.

The trend to the substitution of capital for labour is especially noticeable in the United States, for example, where capital accounts for a steadily increasing proportion of farm inputs. In the United States in 1940, capital comprised 29 percent of farm inputs, labour 54 percent, and land 17 percent; by 1976 capital accounted for 62 percent of farm inputs, labour 16 percent, and land 22 percent. Capital typically replaces labour when large machines do the work of several men using smaller implements; when chemicals replace the scythe and hoe for weed control; when milking parlours, pipelines, and bulk tanks replace handmilking operations; when a mechanized installation replaces the fork and bushel basket in dairy, beef, or hog feeding; when automated sprinklers bring irrigation water to crops; when cisterns and lagoons handle animal waste; when combines and forced-air crop drying speed the harvesting of small grain; and in similar substitutions.

The technical knowledge that a modern large-scale farm manager must possess is frequently held to be far greater than that required of most businessmen with equal investment; the capital required to operate such a farm is beyond the reach of many. In consequence, financial-management techniques resembling those of industry are often employed. Capital is imported from the outside; production is scheduled to meet quantity, grade, and timing requirements; and labour is given specific tasks, as in a factory.

Recognizing the economic benefits of large-scale agriculture, many underdeveloped countries have attempted to create conditions for its existence. National governments, often with outside help, have financed large-scale development programs, involving irrigation or improvement of huge acreages by means of dams, drainage facilities, and canals, and these have revolutionized the lives of many traditional farm managers within the space of a few years. Improvements in crops and livestock, marketing techniques and organization, and transport and power have in some cases increased agricultural productivity and income several times over. Since capital and management have been in the hands of government, the traditional farm manager has, however, often lost some of his independence, and not all such programs have succeeded. Poor planning and management by government authorities and resistance from the farmers themselves have led to some expensive failures.

The commodity market

Reducing market risks. The marketplace for agricultural commodities is exceptionally risky for three important reasons. First, no single farm producer can place or withhold enough of a single item on the market to affect the market price; second, the quantity of a commodity taken off the market does not increase in proportion to price declines; third, the farm manager cannot respond to falling prices by quickly switching production from an unprofitable item to a profitable one. To reduce his risks and safeguard profits, the farm manager may specialize or diversify depending on conditions; he may also use the futures market (see below).

A specialized farm manager concentrates his effort on the production of one item such as wheat, cotton, milk, eggs, or fruit. By such specialization he can realize the benefits of large-scale production and can make the most money from an enterprise in which he is highly skilled. On the other hand, the specialist is vulnerable to sudden changes in the market, to plant and animal diseases, and to soil exhaustion resulting from cultivation of a single crop.

Diversification—the spreading of one's talents over more than one farming enterprise—may be accomplished horizontally or vertically. Horizontal diversification means the production of more than one item for sale. In vertical diversification, the farm manager handles raw products after harvest by processing, packaging, transporting, or even selling at retail. A poultry farmer who produces eggs and washes, candles, grades, packages, and markets them at retail is said to be vertically diversified. He has taken on some of the jobs that could have been performed elsewhere, and as a result he generally receives a better return for his efforts.

Programs of agricultural diversification have been carried out by some developing countries, with the government acting as a kind of national farm manager. Upon achieving independence, nations such as Ghana and Nigeria, in West Africa, found their economies highly dependent upon a single raw agricultural export (cocoa for Ghana; palm oil for Nigeria). Sharply falling prices for these commodities or epidemics of plant disease were seen to have disastrous effect on national prosperity. Erosion problems also caused concern. The governments responded by horizontally diversifying into other profitable crops and vertically diversifying in the establishment of industries to process these commodities or turn them into manufactured goods before export.

A capable farm manager may use the futures market to try to minimize his risks. In the futures market, the farm manager contracts with a buyer to deliver a given quantity of some commodity at a specified date in the future for an agreed price. The buyer is often a speculator who hopes that prices will rise, enabling him to sell the commodity or the contract at a profit. Futures markets enable the farm manager to establish in advance a price for a crop or earn payment for holding a crop in storage. Futures markets also permit some farmers to speculate on a price increase without storing a crop, establish in advance the price of livestock feed intended for later use, and establish an advance price for livestock.

SPECIAL CONCERNS OF SCALE

Farm management specifics vary all over the world; it is possible here to cite only some of the most typical practices in several leading agricultural countries.

Large-farm management. Research has shown that large farms produce more efficiently than small farms. In sugarcane production, for example, the most efficient farm may include many thousands of acres or hectares. Yet, a well-managed dairy farm might achieve greatest efficiency with two men and fewer than 100 cows. In the future, as technology advances, the farms that are managed most efficiently will probably be larger than the most efficient farms at present.

Large farms can reduce costs by claiming volume discounts on their purchases. They can negotiate prices on fertilizer, seed, crop chemicals, petroleum products, machinery, and repair services. Large operators also have an advantage in selling their products. Managers of large corn farms, for example, can contract directly with a large processor for an entire year's production of given quantity and quality for a specific date in the future, thus commanding a higher price. The middleman is eliminated, and production, handling, and processing can be prescheduled for greater efficiency. Large farms also have a smaller investment in machinery and buildings per crop acre.

United States. The increase in the capital requirements of United States farms has already been described above. These changes in American agriculture are, to a large degree, the result of a revolution in financial management. Up to about 1930, little outside capital was needed to finance farming operations. Today, capital investment has vastly increased; farmers obtain their production goods and services—land, machines, breeding stock, seed, fertilizer, and other necessities—in a variety of ways.

Meeting capital requirements

Renting land is one way. In contrast to earlier days when land ownership was considered the ideal, renting land is now a widely accepted management practice. Large acreages of corn land in the Corn Belt, wheat land in the Great Plains, and cotton land in California and Arizona are operated by renters. Renting land enables farmers to operate on a much larger scale than would be possible under ownership. Specialized rice growers in the Sacramento Valley of California, who own tractors, tillage tools, and harvesters, receive rice-acreage allotments from the federal government. Such growers own no land, renting it instead from owners who have no rice allotment. Growers prepare the ground, irrigate it with water supplied by the landowner, and contract for application of seed and fertilizer. When the crop is ripe, the growers harvest the rice with their own combines and haul it to a warehouse for drying and storage. In upland areas of the valley, other growers raise tomatoes under contract from a canner, renting their land from a general crop farmer.

Farmers who do not wish to tie up capital in high-priced farm machinery can contract for harvesting of such crops as wheat, corn, grain sorghum, and barley. An airplane operator may seed, fertilize, and apply weed spray for a rice grower. Vegetables, fruit, and nuts may be picked under contract by shipper-packers whose crews move from farm to farm. Similar operations in livestock include sheepshearing, dehorning, branding, and artificial insemination.

Renting machinery and livestock

Rental of machinery is another management device farmers use to obtain the services of equipment too expensive to be owned individually. Rental of livestock also is receiving attention. In the northeastern United States dairy farmers lease cows. The owner of the cows may be a contracting firm, a local bank, or an individual investor for whom the bank serves as agent. The scheme is useful both to older farmers who wish to retire but want to retain their interest in dairying and to young dairy farmers who want to expand but have limited capital.

Soviet Union. Following the Bolshevik Revolution of 1917, large landholdings were expropriated by the state and the land was distributed among the peasants. In 1928 collectivization of Soviet agriculture was initiated on a large scale; a three-part structure composed of state farms (*sovkhoz*), collective farms (*kolkhoz*), and private plots emerged. The state farms were owned, managed, and operated by the state. Workers on state farms were salaried employees of the state; farm managers were state appointees. During the 1960s and '70s state farms increased sharply in numbers. Much of the increase was the result of new state farms being established in the virgin land areas and the consolidation of smaller collective farms into state farms.

The collective farm leased land from the state and was worked by members of the collective under an elected committee that, as the management unit, had the responsibility of organizing land, labour, and capital in accordance with production requirements. For years, payment to collective members consisted of their share of the collective's produce or income from its sale. Each individual's share was determined by a workday unit that took into account the time spent performing a job and the level of skill required for the job. In the last few decades prior to the dissolution of the Soviet Union (in 1991), most collective farms had shifted to a monthly wage similar to that used by state farms.

Private plots up to two acres (0.8 hectare) in size and operated by individual workers occupied less than 3 percent of the planted area in the Soviet Union but produced nearly half the potatoes, 40 percent of the eggs, 20 percent of the meat, and 13 percent of the vegetables.

Though the Soviet farm manager's role did not include primary decision making, there was a trend from the 1960s toward more management autonomy in farm production. The Soviet government promoted greater efficiency in agriculture by increasing the level of inputs and by improving incentives to farm labourers. These measures included financial concessions to farmers and expanded use of fertilizers, pesticides, irrigation, and drainage. The Soviet farm manager performed additional functions that in other countries are carried out by government and welfare officials, such as providing roads, recreation, education, health care, and welfare to members of the collective.

Israel. A unique feature of the management of agriculture in Israel is its cooperative settlements, which evolved as a result of the needs encountered by immigrants who were new both to their surroundings and to farming as a profession.

The two basic types of cooperative settlement are the moshav and kibbutz. A moshav is a village containing up to 150 farm family units and supported by a strong multipurpose cooperative organization. Each family is an economic and social unit, living in its own house and managing and working its own fields. Although each farm family is independent, its social and economic security is ensured by the cooperative structure of the village, whose organization markets the produce, purchases the farm and household equipment, and provides the farmer with credit and other services.

A kibbutz, numbering from 60 to 2,000 members, is a true collective based on common ownership of resources and on pooling of labour and income; it functions as a single democratic unit. Under the supervision of a manager, each member performs an assigned task but receives no salary or wages, because all the members' needs are provided by the kibbutz.

Israel's agriculture is highly organized into farm societies. One society, the Farmer's Federation, has a membership of 7,000 citrus growers. There are plantation development companies and associations of wine, fruit, milk, and cotton producers.

Production for export

Australia. A significant characteristic of farm management in Australia is the emphasis on production for export markets. Since the production of fine wool is the most important rural industry, grazing of sheep is a leading enterprise. Production of wheat, meat, dairy products, and fruit for export also figures large in the nation's agricultural economy. Australian export production is highly organized through statutory marketing authorities. Ten such authorities supervise the marketing of wheat, dairy products, meat, eggs, canned fruits, dried fruits, apples and pears, wine, honey, and wool.

Getting started in almost any farming venture in Australia requires substantial amounts of capital.

Management of small and middle-sized farms. *Canada.* Canadian agriculture consists largely of family farms, managed and operated by the owners. Less than one farm in 100 has hired management. A Canadian farm may vary in size from a factory-type broiler chicken plant of an acre or two (up to one hectare) to a cattle ranch that includes several townships. On a mechanized grain farm a farmer may operate 1,000 acres (400 hectares) or more with very little hired help. While most farmers in Canada own the farms they operate, there is a growing tendency to rent additional land. Current management trends also include increased use of commercial fertilizer and chemicals for pest control.

Farm management practices vary widely. Some farmers who rent land pay cash rent. In other cases the landlord takes a share of the crop or a share of the income from the sale of livestock or milk. On farms where most of the income is derived from the sale of grain, it is common for the tenant to give the landlord one-third of all grain produced. The landlord supplies the land, pays the taxes and fire insurance on the buildings, and provides materials for maintaining buildings and fences. Integration, the management of two or more stages of production and marketing, is spreading, with the trend most noticeable with sugar beets and canning crops.

United Kingdom. British farmers are well known for their efficient management and use of mechanical aids. Milking machines are employed on all but the smallest farms; electricity is widespread; grain combines are common; and there is one tractor for about every 35 acres (14 hectares) of arable land. British farmers also use great quantities of commercial fertilizer per acre, the cost of which is subsidized by the government. The government also subsidizes the cost of lime, eradication of tuberculosis, and construction of silos and other capital equipment and pays part of the cost of voluntary consolidation of small farms into more efficient commercial units.

Several agricultural commodities are subject to the authority of government marketing boards: some buy produce, others control producer–buyer contracts, and still others maintain broad control over marketing conditions. Cereals, potatoes, eggs, sugar beets, and wool are the principal products governed by marketing bodies.

Denmark. In Denmark successful farmer cooperatives play a major management role, extending credit and controlling production, marketing, import, export, purchasing, and sales. Through these cooperatives, Danish farmers enjoy the benefits of large-scale production and distribution despite the small size of individual farms. About 90 percent of Denmark's output of pork and milk and about 50 percent of egg output is marketed cooperatively. The number of farms in Denmark has been declining in recent years, but those remaining are becoming larger. Average size in the late 1970s was 54 acres (22 hectares). The family farm predominates.

Farm management in developing countries. *India.* Farm management practices in India range from the modern and sophisticated to some that have been in use for centuries. Illiteracy, inadequate water, unreliable power supplies, poor transportation and communications, making the timely acquistition of supplies and marketing of produce difficult—all hamper the development of modern farm management practices. For example, many farmers are unable to read the directions on a sack of fertilizer, to write an application for a production loan, or to calculate their profit and loss. Where progress has been made in introducing improved farm management techniques, visual and oral methods of instruction and training are being used successfully. Training techniques include on-farm demonstrations, farmer exchange programs, tours, short courses, literacy classes, exhibits, and audio–visual vans.

Republic of Zaire. Shifting cultivation is the typical method of farming in the Republic of Zaire. The native farmer clears two or three acres (about one hectare) in the forest or savanna, crops it until the fertility of the land declines, then moves on to another area. Fertilizer, insecticides, and fungicides are not generally available.

A land-settlement plan, called the paysannat system, in which strips of cultivated land were alternated with bush and grassland, was introduced in the 1930s to increase production. This system, however, has disintegrated since independence due to the lack of management personnel and government extension services and disruption of marketing channels. Often side by side with traditional farms are large modern plantations owned, managed, and operated by individual Europeans and corporations. Plantation crop yields are two to 10 times those of indigenous farms, probably pointing the direction of future development.

(M.E.Bl.)

PRINCIPLES AND PRACTICES OF PLANT CULTIVATION

Plant breeding

In its modern form, plant breeding involves the application of genetic principles to produce plants that are more useful to man. This is accomplished by selecting plants that man finds desirable, economically or aesthetically, by controlling the mating of the selected individuals and by selecting desirable individuals among the progeny. These processes, repeated over many generations, can change the hereditary makeup and value of a plant population far beyond the natural limits of previously existing populations. This article emphasizes the application of genetic principles to the improvement of plants; the biological factors underlying plant breeding are dealt with in the article GENETICS AND HEREDITY.

Historical background

Plant breeding is an ancient activity of man, dating back to the very beginnings of agriculture. Probably soon after the earliest domestications of cereal grains, man began to recognize degrees of excellence among the plants in his fields and saved seed from the best plants for planting new crops. Such tentative selective methods were the forerunners of early plant-breeding procedures.

The results of early plant-breeding procedures were conspicuous. Most present-day varieties are so modified from their wild progenitors they are unable to survive in nature. Indeed, in some cases, the cultivated forms are so strikingly different from existing wild relatives that it is even difficult to identify their ancestors. These remarkable transformations were accomplished by early plant breeders in a very short time from an evolutionary point of view, and the rate of change was probably greater than for any other evolutionary event.

Scientific plant breeding dates back hardly more than 50 years. The role of pollination and fertilization in the process of reproduction was not widely appreciated even 100 years ago, and it was not until the early part of the 20th century that the laws of genetic inheritance were recognized and a beginning was made toward applying them to the improvement of plants. One of the major facts that has emerged during the short history of scientific breeding is that an enormous wealth of genetic variability exists in the plants of the world and that only a start has been made in tapping its potential.

GOALS

The plant breeder usually has in mind an ideal plant that combines a maximum number of desirable characteristics. These characteristics may include resistance to diseases and insects; tolerance to heat and frost; appropriate size, shape, and time to maturity; and many other general and specific traits that contribute to improved adaptation to the environment, ease in growing and handling, greater yield, and better quality. The breeder of fancy show plants must also consider aesthetic appeal. Thus the breeder can rarely focus attention on any one characteristic but must take into account the manifold traits that make the plant more useful in fulfilling the purpose for which it is grown.

Increase of yield. One of the aims of virtually every breeding project is to increase yield. This can often be brought about by selecting obvious morphological variants. One example is the selection of dwarf, early maturing varieties of rice. These dwarf varieties are sturdy and give a greater yield of grain. Furthermore, their early maturity frees the land quickly, often allowing an additional planting of rice or other crop the same year.

Another way of increasing yield is to develop varieties resistant to diseases and insects. In many cases the development of resistant varieties has been the only practical method of pest control. Perhaps the most important feature of resistant varieties is the stabilizing effect they have on production and hence on steady food supplies. Varieties tolerant to drought, heat, or cold provide the same benefit.

Modifications of range and constitution. Another common goal of plant breeding is to extend the area of production of a crop species. A good example is the modification of grain sorghum since its introduction to the United States about 100 years ago. Of tropical origin, grain sorghum was originally confined to the southern Plains area and the Southwest, but earlier maturing varieties were developed until grain sorghum is now an important crop as far north as North Dakota.

Varieties suited to mechanized farming

Development of crop varieties suitable for mechanized agriculture has become a major goal of plant breeding in recent years. Uniformity of plant characters is very important in mechanized agriculture because field operations are much easier when the individuals of a variety are similar in time of germination, growth rate, size of fruit, and so on. Uniformity in maturity is, of course, essential when crops such as tomatoes and peas are harvested mechanically.

The nutritional quality of plants can be greatly improved by breeding. For example, it is possible to breed varieties of corn (maize) much higher in lysine than previously existing varieties. Breeding high-lysine maize varieties for those areas of the world where maize is the major source of this nutritionally essential amino acid has become a major goal in plant breeding.

In breeding ornamentals, attention is paid to such factors as longer blooming periods, improved keeping qualities of flowers, general thriftiness, and other features that contribute to usefulness and aesthetic appeal. Novelty itself is often a virtue in ornamentals, and the spectacular, even the bizarre, is often sought.

EVALUATION OF PLANTS

The appraisal of the value of plants so that the breeder can decide which individuals should be discarded and which allowed to produce the next generation is a much more difficult task with some traits than with others.

Qualitative characters. The easiest characters, or traits, to deal with are those involving discontinuous, or qualitative, differences that are governed by one or a few major genes. Many such inherited differences exist, and they frequently have profound effects on plant value and utilization. Examples are starchy versus sugary kernels (characteristic of field and sweet corn, respectively) and determinant versus indeterminant habit of growth in green beans (determinant varieties are adapted to mechanical harvesting). Such differences can be seen easily and evaluated quickly, and the expression of the traits remains the same regardless of the environment in which the plant grows. Traits of this type are termed highly heritable.

Quantitative characters. In other cases, however, plant traits grade gradually from one extreme to another in a continuous series, and classification into discrete classes is not possible. Such variability is termed quantitative. Many traits of economic importance are of this type; *e.g.*, height, cold and drought tolerance, time to maturity, and, in particular, yield. These traits are governed by many genes, each having a small effect. Although the distinction between the two types of traits is not absolute, it is nevertheless convenient to designate qualitative characters as those involving discrete differences and quantitative characters as those involving a graded series.

Controlling quantitative characters

Quantitative characters are much more difficult for the breeder to control, for three main reasons: (1) the sheer numbers of the genes involved make hereditary change slow and difficult to assess; (2) the variations of the traits involved are generally detectable only through measurement and exacting statistical analyses; and (3) most of the variations are due to the environment rather than to genetic endowment; for example, the heritability of certain traits is less than 5 percent, meaning that 5 percent of the observed variation is caused by genes and 95 percent is caused by environmental influences.

It follows that carefully designed experiments are required to distinguish plants that are superior because they carry desirable genes from those that are superior because they happen to grow in a favourable site.

METHODS OF PLANT BREEDING

Mating systems. Plant mating systems devolve about the type of pollination, or transferal of pollen from flower to flower (see the article REPRODUCTION AND REPRODUCTIVE SYSTEMS: *Pollination*). A flower is self-pollinated (a "selfer") if pollen is transferred to it from any flower of the same plant and cross-pollinated (an "outcrosser" or "outbreeder") if the pollen comes from a flower on a different plant. About half of the more important cultivated plants are naturally cross-pollinated, and their reproductive systems include various devices that encourage cross-pollination; *e.g.*, protandry (pollen shed before the ovules are mature, as in the carrot and walnut), dioecy (stamens and pistils borne on different plants, as in the date palm, asparagus, and hops), and genetically determined self-incompatibility (inability of pollen to grow on the stigma of the same plant, as in white clover, cabbage, and many other species).

Other plant species, including a high proportion of the most important cultivated plants such as wheat, barley, rice, peas, beans, and tomatoes, are predominantly self-pollinating. There are relatively few reproductive mechanisms that promote self-pollination; the most positive of which is failure of the flowers to open (cleistogamy), as in certain violets. In barley, wheat, and lettuce the pollen is shed before or just as the flowers open; and in the tomato pollination follows opening of the flower, but the stamens form a cone around the stigma. In such species there is always a risk of unwanted cross-pollination.

Control of breeding

In controlled breeding procedures it is imperative that pollen from the desired male parent, and no other pollen, reaches the stigma of the female parent. When stamens and pistils occur in the same flower, the anthers must be removed from flowers selected as females before pollen is shed. This is usually done with forceps or scissors. Protection must also be provided from "foreign" pollen. The most common method is to cover the flower with a plastic or paper bag. When the stigma of the female parent becomes receptive, pollen from the desired male parent is transferred to it, often by breaking an anther over the stigma, and the protective bag is replaced. The production of certain hybrids is, therefore, tedious and expensive because it often requires a series of delicate, exacting, and properly timed hand operations. When male and female parts occur in separate flowers, as in corn (maize), controlled breeding is easier.

A cross-pollinated plant, which has two parents, each of which is likely to differ in many genes, produces a diverse population of plants hybrid (heterozygous) for many traits. A self-pollinated plant, which has only one parent, produces a more uniform population of plants pure breeding (homozygous) for many traits. Thus, in contrast to outbreeders, self-breeders are likely to be highly homozygous and hence true breeding for a specified trait.

Breeding self-pollinated species. The breeding methods that have proved successful with self-pollinated species are (1) mass selection; (2) pure-line selection; (3) hybridization, with the segregating generations handled by the pedigree method, the bulk method, or by the backcross method; and (4) development of hybrid varieties.

Mass selection. In mass selection, seeds are collected from (usually a few dozen to a few hundred) desirable appearing individuals in a population, and the next generation is sown from the stock of mixed seed. This procedure, sometimes referred to as phenotypic selection, is based on how each individual looks. Mass selection has been used widely to improve old "land" varieties, varieties that have been passed down from one generation of farmers to the next over long periods.

An alternative approach that has no doubt been practiced for thousands of years is simply to eliminate undesirable types by destroying them in the field. The results are similar whether superior plants are saved or inferior plants are eliminated: seeds of the better plants become the planting stock for the next season.

A modern refinement of mass selection is to harvest the best plants separately and to grow and compare their progenies. The poorer progenies are destroyed and the seeds of the remainder are harvested. It should be noted that selection is now based not solely on the appearance of the parent plants but also on the appearance and performance of their progeny. Progeny selection is usually more effective than phenotypic selection when dealing with quantitative characters of low heritability. It should be noted, however, that progeny testing requires an extra generation; hence gain per cycle of selection must be double that of simple phenotypic selection to achieve the same rate of gain per unit time.

Mass selection, with or without progeny test, is perhaps the simplest and least expensive of plant-breeding procedures. It finds wide use in the breeding of certain forage species, which are not important enough economically to justify more detailed attention.

Pure-line selection. Pure-line selection generally involves three more or less distinct steps: (1) numerous superior appearing plants are selected from a genetically variable population; (2) progenies of the individual plant selections are grown and evaluated by simple observation, frequently over a period of several years; and (3) when selection can no longer be made on the basis of observation alone, extensive trials are undertaken, involving careful measurements to determine whether the remaining selections are superior in yielding ability and other aspects of performance. Any progeny superior to an existing variety is then released as a new "pure-line" variety. Much of the success of this method during the early 1900s depended on the existence of genetically variable land varieties that were waiting to be exploited. They provided a rich source of superior pure-line varieties, some of which are still represented among commercial varieties. In recent years the pure-line method as outlined above has decreased in importance in the breeding of major cultivated species;

Exploitation of sports

however, the method is still widely used with the less important species that have not yet been heavily selected. A variation of the pure-line selection method that dates back centuries is the selection of single-chance variants, mutations or "sports" in the original variety. A very large number of varieties that differ from the original strain in characteristics such as colour, lack of thorns or barbs, dwarfness, and disease resistance have originated in this fashion.

Hybridization. During the 20th century planned hybridization between carefully selected parents has become dominant in the breeding of self-pollinated species. The object of hybridization is to combine desirable genes found in two or more different varieties and to produce pure-breeding progeny superior in many respects to the parental types.

Genes, however, are always in the company of other genes in a collection called a genotype. The plant breeder's problem is largely one of efficiently managing the enormous numbers of genotypes that occur in the generations following hybridization. As an example of the power of hybridization in creating variability, a cross between hypothetical wheat varieties differing by only 21 genes is capable of producing more than 10,000,000,000 different genotypes in the second generation. At spacings normally used by farmers, more than 50,000,000 acres would be required to grow a population large enough to permit every genotype to occur in its expected frequency. While the great majority of these second generation genotypes are hybrid (heterozygous) for one or more traits, it is statistically possible that 2,097,152 different pure-breeding (homozygous) genotypes can occur, each potentially a new pure-line variety. These numbers illustrate the importance of efficient techniques in managing hybrid populations, for which purpose the pedigree procedure is most widely used.

Pedigree breeding starts with the crossing of two genotypes, each of which have one or more desirable characters lacked by the other. If the two original parents do not provide all of the desired characters, a third parent can be included by crossing it to one of the hybrid progeny of the first generation (F_1). In the pedigree method superior types are selected in successive generations, and a record is maintained of parent–progeny relationships.

The F_2 generation (progeny of the crossing of two F_1 individuals) affords the first opportunity for selection in pedigree programs. In this generation the emphasis is on the elimination of individuals carrying undesirable major genes. In the succeeding generations the hybrid condition gives way to pure breeding as a result of natural self-pollination, and families derived from different F_2 plants begin to display their unique character. Usually one or two superior plants are selected within each superior family in these generations. By the F_5 generation the pure-breeding condition (homozygosity) is extensive, and emphasis shifts almost entirely to selection between families. The pedigree record is useful in making these eliminations. At this stage each selected family is usually harvested in mass to obtain the larger amounts of seed needed to evaluate families for quantitative characters. This evaluation is usually carried out in plots grown under conditions that simulate commercial planting practice as closely as possible. When the number of families has been reduced to manageable proportions by visual selection, usually by the F_7 or F_8 generation, precise evaluation for performance and quality begins. The final evaluation of promising strains involves (1) observation, usually in a number of years and locations, to detect weaknesses that may not have appeared previously; (2) precise yield testing; and (3) quality testing. Many plant breeders test for five years at five representative locations before releasing a new variety for commercial production.

Bulk-population breeding

The bulk-population method of breeding differs from the pedigree method primarily in the handling of generations following hybridization. The F_2 generation is sown at normal commercial planting rates in a large plot. At maturity the crop is harvested in mass, and the seeds are used to establish the next generation in a similar plot. No record of ancestry is kept. During the period of bulk propagation natural selection tends to eliminate plants having poor survival value. Two types of artificial selection also are often applied: (1) destruction of plants that carry undesirable major genes and (2) mass techniques such as harvesting when only part of the seeds are mature to select for early maturing plants or the use of screens to select for increased seed size. Single plant selections are then made and evaluated in the same way as in the pedigree method of breeding. The chief advantage of the bulk population method is that it allows the breeder to handle very large numbers of individuals inexpensively.

Often an outstanding variety can be improved by transferring to it some specific desirable character that it lacks. This can be accomplished by first crossing a plant of the superior variety to a plant of the donor variety, which carries the trait in question, and then mating the progeny back to a plant having the genotype of the superior parent. This process is called backcrossing. After five or six backcrosses the progeny will be hybrid for the character being transferred but like the superior parent for all other genes. Selfing the last backcross generation, coupled with selection, will give some progeny pure breeding for the genes being transferred. The advantages of the backcross method are its rapidity, the small number of plants required, and the predictability of the outcome. A serious disadvantage is that the procedure diminishes the occurrence of chance combinations of genes, which sometimes leads to striking improvements in performance.

Hybrid vigour

Hybrid varieties. The development of hybrid varieties differs from hybridization in that no attempt is made to produce a pure-breeding population; only the F_1 hybrid plants are sought. The F_1 hybrid of crosses between different genotypes is often much more vigorous than its parents. This hybrid vigour, or heterosis, can be manifested in many ways, including increased rate of growth, greater uniformity, earlier flowering, and increased yield, the last being of greatest importance in agriculture.

By far the greatest development of hybrid varieties has been in corn (maize), primarily because its male flowers (tassels) and female flowers (incipient ears) are separate and easy to handle, thus proving economical for the production of hybrid seed. The production of hand-produced F_1 hybrid seed of other plants, including ornamental flowers, has been economical only because greenhouse growers and home gardeners have been willing to pay high prices for hybrid seed.

Recently, however, a built-in cellular system of pollination control has made hybrid varieties possible in a wide range of plants, including many that are self-pollinating, such as sorghums. This system, called cytoplasmic male sterility, or cytosterility (Figure 1), prevents normal maturation or function of the male sex organs (stamens) and results in defective pollen or none at all. It obviates the need for removing the stamens either by hand or by machine. Cytosterility depends on the interaction between male sterile genes ($R + r$) and factors found in the cytoplasm of the female sex cell. The genes are derived from each parent in the normal Mendelian fashion, but the cytoplasm (and its factors) is provided by the egg only; therefore, the inheritance of cytosterility is determined by the female parent. All plants with fertile cytoplasm produce viable pollen, as do plants with sterile cytoplasm but at least one R gene; plants with sterile cytoplasm and two r genes are male sterile (produce defective pollen).

The production of F_1 hybrid seed between two strains is accomplished by interplanting a sterile version of one strain (say A) in an isolated field with a fertile version of another strain (B). Since strain A produces no viable pollen, it will be pollinated by strain B, and all seeds produced on strain A plants must therefore be F_1 hybrids between the strains. The F_1 hybrid seeds are then planted to produce the commercial crop. Much of the breeder's work in this process is in developing the pure-breeding sterile and fertile strains to begin the hybrid seed production.

Breeding cross-pollinated species. The most important methods of breeding cross-pollinated species are (1) mass selection; (2) development of hybrid varieties; and (3) development of synthetic varieties. Since cross-pollinated species are naturally hybrid (heterozygous) for many traits and lose vigour as they become purebred (homozygous),

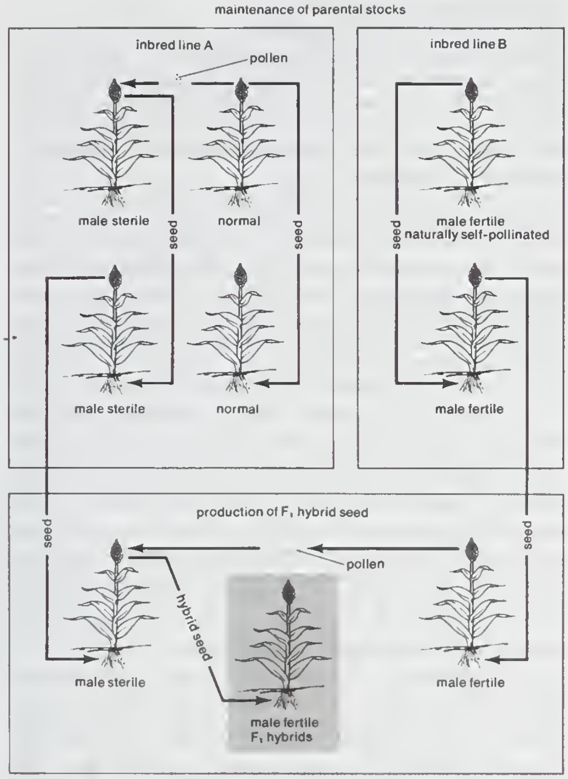

Figure 1: Production of hybrid seed in sorghum using cytoplasmic male sterility.

a goal of each of these breeding methods is to preserve or restore heterozygosity.

Mass selection. Mass selection in cross-pollinated species takes the same form as in self-pollinated species; *i.e.*, a large number of superior appearing plants are selected and harvested in bulk and the seed used to produce the next generation. Mass selection has proved to be very effective in improving qualitative characters, and, applied over many generations, it is also capable of improving quantitative characters, including yield, despite the low heritability of such characters. Mass selection has long been a major method of breeding cross-pollinated species, especially in the economically less important species.

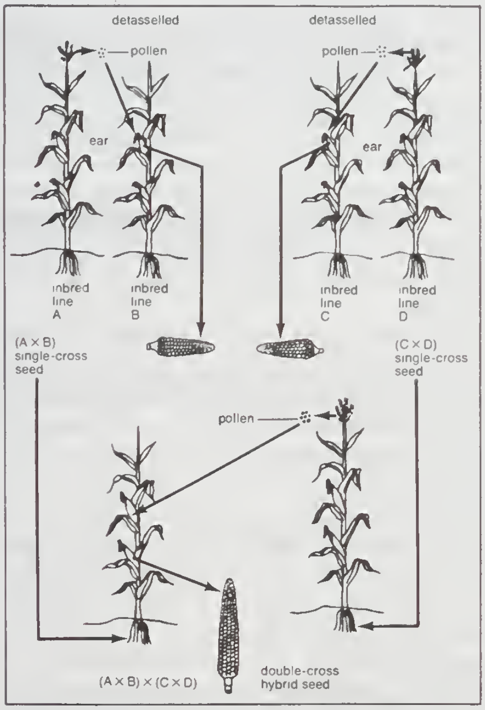

Figure 2: The crossing of inbred lines of corn (maize) to produce single crosses and the crossing of single crosses to produce double-cross hybrid seed.

Production of hybrid corn

Hybrid varieties. The outstanding example of the exploitation of hybrid vigour through the use of F_1 hybrid varieties has been with corn (maize). The production of a hybrid corn variety (Figure 2) involves three steps: (1) the selection of superior plants; (2) selfing for several generations to produce a series of inbred lines, which although different from each other are each pure-breeding and highly uniform; and (3) crossing selected inbred lines. During the inbreeding process the vigour of the lines decreases drastically, usually to less than half that of field-pollinated varieties. Vigour is restored, however, when any two unrelated inbred lines are crossed, and in some cases the F_1 hybrids between inbred lines are much superior to open-pollinated varieties. An important consequence of the homozygosity of the inbred lines is that the hybrid between any two inbreds will always be the same. Once the inbreds that give the best hybrids have been identified, any desired amount of hybrid seed can be produced.

Pollination in corn (maize) is by wind, which blows pollen from the tassels to the styles (silks) that protrude from the tops of the ears. Thus controlled cross-pollination on a field scale can be accomplished economically by interplanting two or three rows of the seed parent inbred with one row of the pollinator inbred and detasselling the former before it sheds pollen. In practice most hybrid corn is produced from "double crosses," in which four inbred lines are first crossed in pairs (A × B and C × D) and then the two F_1 hybrids are crossed again (A × B) × (C × D). The double-cross procedure has the advantage that the commercial F_1 seed is produced on the highly productive single cross A × B rather than on a poor-yielding inbred, thus reducing seed costs. In recent years cytoplasmic male sterility, described earlier, has been used to eliminate detasselling of the seed parent, thus providing further economies in producing hybrid seed.

D F Jones, *Genetics*, no 9 (1924)

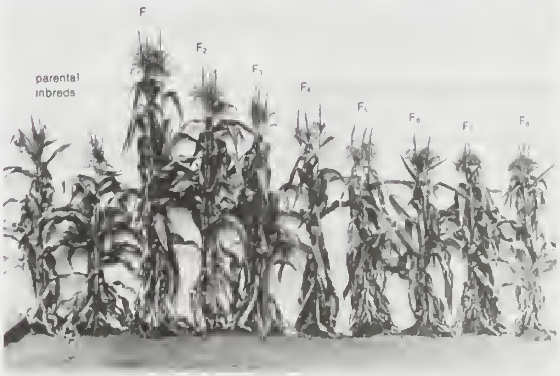

Figure 3: *Heterosis followed by decline in vigour in corn (maize).*
Representative plants of the two parental inbreds are at left. To their right are vigorous F_1 hybrids and the F_2 through F_8 selfed generations. The decline in vigour from F_1 through F_8 is similar to that observed when plants from open-pollinated varieties are self-pollinated.

Much of the hybrid vigour exhibited by F_1 hybrid varieties is lost in the next generation. Consequently, seed from hybrid varieties is not used for planting stock but the farmer purchases new seed each year from seed companies.

Perhaps no other development in the biological sciences has had greater impact on increasing the quantity of food supplies available to the world's population than has the development of hybrid corn (maize). Hybrid varieties in other crops, made possible through the use of male sterility, have also been dramatically successful and it seems likely that use of hybrid varieties will continue to expand in the future.

Synthetic varieties. A synthetic variety is developed by intercrossing a number of genotypes of known superior combining ability—*i.e.*, genotypes that are known to give superior hybrid performance when crossed in all combinations. (By contrast, a variety developed by mass selection is made up of genotypes bulked together without having undergone preliminary testing to determine their performance in hybrid combination.) Synthetic varieties are known for their hybrid vigour and for their ability to produce usable seed for succeeding seasons. Because of these advantages, synthetic varieties have become increasingly favoured in the growing of many species, such as the forage crops, in which expense prohibits the development or use of hybrid varieties.

Distribution and maintenance of new varieties. The benefits of superior new varieties obviously cannot be realized until sufficient seed has been produced to permit commercial production. Although the primary function of the plant breeder is to develop new varieties, he usually also carries out an initial small-scale seed increase. Seed thus produced is called breeders seed. The next stage is the multiplication of breeders seed to produce foundation seed. Production of foundation seed is usually carried out by seed associations or institutes, whose work is regulated by government agencies. The third step is the production of certified seed, the progeny of foundation seed, produced on a large scale by specialized seed growers for general sale to farmers and gardeners. Certified seed must be produced and handled in such a way as to meet the standards set by the certifying agency (usually a seed association). Seed associations are also usually responsible for maintaining the purity of new varieties once they have been released for commercial production.

Breeders, foundation, and certified seed

The distribution of new varieties developed by commercial plant-breeding companies is often through seed associations, but many reputable companies market their products without following the official certification process. In some countries, particularly in Europe, new varieties can be patented for periods up to 15 years or more, during which time the breeder has an exclusive right to reproduce and sell the variety. (R.W.A.)

Irrigation and drainage

Irrigation is the artificial application of water to land. Drainage is the artificial removal of excess water from land. Though either practice may be, and both often are, used for nonagricultural purposes to improve the environment, this section is limited to their major application, to agriculture. Some land requires irrigation or drainage before it is possible to use it for any agricultural production; other land profits from either practice to increase agricultural production. Some land, of course, does not need either practice.

Irrigation and drainage improvements are not necessarily mutually exclusive. Often both may be required together to assure sustained, high-level production of crops.

MODERN IRRIGATION-SYSTEM PLANNING AND CONSTRUCTION

Water supply. The first consideration in planning an irrigation project is developing a water supply. Water supplies may be classified as surface or subsurface. Though both surface and subsurface water come from precipitation such as rain or snow, it is far more difficult to determine the origin of subsurface water.

In planning a surface water supply, extensive studies must be made of the flow in the stream or river that will be used. If the streamflow has been measured regularly over a long period, including times of drought and flood, the studies are greatly simplified. From streamflow data, determinations can be made of the minimum, maximum, average daily, and average monthly flows; the size of dams, spillways, and downstream channel; and the seasonal and carry-over storage needed. If adequate streamflow data are not available, the streamflow may be estimated from rain and snow data, or from flow data from nearby streams that have similar climatic and physiographic conditions.

Studying streamflow

The quality, as well as the quantity, of surface water is a factor. The two most important considerations are the amount of silt carried and the kind and amount of salts dissolved in the water. If the silt content is high, sediment will be deposited in the reservoir, increasing maintenance costs and decreasing useful life periods. If the salt concentration is high, it may damage crops or accumulate in the soil and eventually render it unproductive.

Subsurface sources of water must be as carefully investigated as surface sources. In general, less is known about subsurface supplies of water than about surface supplies, so, therefore, subsurface supplies are harder to investigate. Engineers planning a project need to know the extent of the basic geological source of water (the aquifer), as well as the amount the water level is lowered by pumping and the rate of recharge of the aquifer. Often the only way for the engineer to obtain these data reliably is to drill test wells and make onsite measurements. Usually, a project is planned so as not to use more subsurface water than is recharged. Otherwise, the water is said to be "mined," meaning that as a natural resource it is being used up.

Two sources of water not often thought of by the layman are dew and sewage. In certain parts of the world, Israel and part of Australia, for example, where atmospheric conditions are right, sufficient dew may be trapped at night to provide water for irrigation. Elsewhere the supply of waste water from some industries and municipalities is sufficient to irrigate relatively small acreages. Recently, due to greater emphasis on purer water in streams, there has been increased interest in this latter practice.

In some countries (Egypt for example) sewage is a valuable source of water. In others, such as the United States, irrigation is looked upon as a means of disposing of sewer water as a final step in the waste-treatment process. Unless the water contains unusual chemical salts, such as sodium, it is generally of satisfactory quality for agricultural irrigation. Where the practice is used primarily as a means of disposal, large areas are involved and the choice of crop is critical. Usually only grass or trees can withstand the year-round applications.

Determining water rights

Before a water supply can be assured, the right to it must be determined. Countries and states have widely varying laws and customs that determine ownership of water. If the development of a water supply is for a single purpose, then the determination of ownership may be relatively simple; but if the development is multipurpose, as most modern developments are, ownership may be difficult to determine, and agreements must be worked out among countries, states, municipalities, and private owners.

The area that can be irrigated by a water supply depends on the weather, the type of crop grown, and the soil. Numerous methods have been developed to evaluate these factors and predict average annual volume of rainfall needed. Some representative annual amounts of rainfall needed for cropland in the western United States are 12 to 30 inches (305 to 760 millimetres) for grain and 24 to 60 inches (610 to 1,525 millimetres) for forage. In the Near East, cotton needs about 36 inches (915 millimetres), whereas rice may require two to three times that amount.

In humid regions of the United States, where irrigation supplements rainfall, grain crops may require six to nine inches (150 to 230 millimetres) of water. In addition to satisfying the needs of the crop, allowances must be made for water lost directly to evaporation and during transport to the fields.

Transport systems. The type of transport system used for an irrigation project is often determined by the source of the water supply. If a surface water supply is used, a large canal or pipeline system is usually required to carry the water to the farms because the reservoir is likely to be distant from the point of use. If subsurface water drawn from wells is used, a much smaller transport system is needed, though canals or pipelines may be used. The transport system will depend as far as possible on gravity flow, supplemented if necessary by pumping. From the mains, water flows into branches, or laterals, and finally to distributors that serve groups of farms. Many auxiliary structures are required, including weirs (flow-diversion dams), sluices, and other types of dams. Canals are normally lined with concrete to prevent seepage losses, control weed growth, eliminate erosion hazards, and reduce maintenance. The most common type of concrete canal construction is by slip forming. In this type of construction, the canal is excavated to the exact cross section desired and the concrete placed on the earth sides and bottom.

Water pipelines

Pipelines may be constructed of many types of material. The larger lines are usually concrete whereas laterals may be concrete, cement–asbestos, rigid plastic, aluminum, or steel. Although pipelines are more costly than open conduits, they do not require land after construction, suffer little evaporation loss, and are not troubled by algae growth.

Water application. After water reaches the farm it may be applied by surface, subsurface, or sprinkler-irrigation methods. Surface irrigation is normally used only where the land has been graded so that uniform slopes exist (see Figure 5). Land grading is not necessary for other methods. Each method includes several variations, only the more common of which are considered here.

Surface irrigation systems are usually classed as either flood or furrow systems. In the flood system, water is applied at the edge of a field and allowed to move over the entire surface to the opposite side of the field. Grain and forage crops are quite often irrigated by flood techniques. The furrow system is used for row crops such as corn (maize), cotton, sugar beets, and potatoes. Furrows are plowed between crop rows and the water is run in the furrows. In either type of surface irrigation systems, wastewater ditches at the lower edge of the fields permit excess water to be removed for use elsewhere and to prevent waterlogging.

Figure 5: Surface methods of applying irrigation water to field crops.

Subirrigation is a less common method. An impermeable layer must be located below, but near, the root zone of the crop so that water is trapped in the root zone. If this condition exists, water is applied to the soil through tile drains or ditches.

In recent years sprinklers have been used increasingly to irrigate agricultural land. Little or no preparation is needed, application rates can be controlled, and the system may be used for frost protection and the application of chemicals. Sprinklers range from those that apply water in the form of a mist to those that apply an inch or more per hour.

Evaporation and seepage control. Various techniques have been tried to reduce losses of irrigation water. Two major sources of loss, particularly from surface supplies and surface systems, are evaporation and seepage from reservoirs and canals. Many studies have been made of techniques to suppress evaporation. One of the more promising appears to be application of a special alcohol film on the surface, which retards evaporation by about 30 percent and does not reduce the quality of the water. The primary problem in its use is that it is fragile; a strong wind can blow it apart and expose the water to evaporation.

Seepage has largely been controlled by lining main and distribution channels with impervious material, typically concrete. Other materials used are asphalt and plastic film, though plastic tends to deteriorate if it is exposed to sunlight.

Typical systems. The typical surface irrigation system utilizes a publicly developed water supply—*e.g.*, a river-basin reservoir. The public project also constructs the main canals to take water from the reservoir to the agricultural land. In general the canals flow by gravity, but lift stations are often required. Supply and field canals are used to bring the water to the individual field, where it is applied to the land either by furrow or by flooding method.

Sprinkler irrigation

Until recently most sprinkler-irrigation systems depended on privately developed water supplies, but many modern sprinkler systems have been able to draw on public water supplies. In either case, a pump is required to pump water from a large (1,000 gallons, or 3,785 litres, per minute and larger) well or a supply canal. The water goes into the system main and thence to a sprinkler unit. Many automatic or semiautomatic moving sprinkler systems travel over the field applying water. Two common units are the so-called centre pivot and the travelling sprinkler. The centre-pivot unit is anchored at the centre of the field; a long lateral (arm) with sprinklers mounted on it sweeps the field in a circle. The system has the disadvantage of missing the corners of a square field. A travelling sprinkler is mounted on a trailer and propelled across the field in a lane that has been left unplanted. The unit drags a flexible hose connected to the main supply line. When it reaches the end of the lane, it is automatically shut off and can be moved to the next lane. Despite some shortcomings, all sprinkler systems are effective in applying a controlled amount of water at a high level of efficiency with a minimum of labour.

MODERN DRAINAGE-SYSTEM PLANNING AND CONSTRUCTION

Planning a system. The planning and design of drainage systems is not an exact science. Although there have been many advances in soil and crop science, techniques have not been developed for combining the basic principles involved into precise designs. One of the primary reasons for difficulty in applying known theory is the capricious variability of natural soil in contrast to the idealized soils required to develop a theory.

The type of drainage system designed depends on many factors, but the most important is the type of soil, which determines whether water will move through rapidly enough to use subsurface drainage. Soils that have a high percentage of sand- and silt-size particles and a low percentage of clay-size particles usually will transmit water rapidly enough to make subsurface drainage feasible. Soils that are high in clay-size particles usually cannot be drained by subsurface improvements. It is essential to consider soil properties to a depth of five to six feet (1.5 to 1.8 metres) because the layer in the soil that transmits water the slowest controls the design, and subsurface improvements may be installed to these depths.

The topography or slope of the land is also important. In many cases, land in need of drainage is so flat that a contour map showing elevations 12 inches (30 centimetres) or six inches (15 centimetres) apart is used to identify trouble spots and possible outlets for drainage water. Often an outlet can be developed only by collective community action. The rainfall patterns, the crops to be grown, and the normal height of the water table also are considered. If heavy rainfall is not probable during critical stages of crop growth, less extensive drainage improvements may suffice. The capacity of the system is governed in part by the growth pattern of the crop, its planting date, critical stages of growth, tolerance of excess water, harvest date, and value.

In some areas the normal water level in the soil is high, in others low; this variable is always investigated before a drainage system is planned.

Types of drainage systems. Drainage systems may be divided into two categories, surface and subsurface. Each has several components with similar functions but different names. At the lower, or disposal, end of either system is an outlet. In order of decreasing size, the components of a surface system are the main collection ditch, field ditch, and field drain; and for a subsurface system, main, submain, and lateral conduits from the submain. The outlet is the point of disposal of water from the system; the main carries water to the outlet; the submain or field ditch collects water from a number of smaller units and carries it to the main; and the lateral or field drain, the smallest unit of the system, removes the water from the soil.

Drainage system outlet

The outlet for a drainage system may be a natural stream or river or a large constructed ditch. A constructed ditch usually is trapezoidal in section with side banks flat enough to be stable. Grass may be grown on the banks, which are kept clear of trees and brush that would interfere with the flow of water.

A surface drainage system removes water from the surface of the soil and to approximately the bottom of the field ditches. A surface system is the only means for drainage improvement on soils that transmit water slowly. Individual surface drains also are used to supplement subsurface systems by removing water from ponded areas.

The field drains of a surface system may be arranged in many patterns. Probably the two most widely used are parallel drains and random drains. Parallel drains are channels running parallel to one another at a uniform spacing of a few to several hundred feet apart, depending on the soil and the slope of the land. Random drains are channels that run to any low areas in the field. The parallel system provides uniform drainage, whereas the random system drains only the low areas connected by channels. In either case the channels are shallow with flat sides and may be farmed like the rest of the field. Crops are usually planted perpendicular to the channels so that the water flows between the rows to the channels.

Some land grading of the fields where surface drains are installed is usually essential for satisfactory functioning. Land grading is the shaping of the field so that the land slopes toward the drainage channels. The slope may be uniform over the entire field or it may vary from part to part. Before the advent of the digital computer, the calculations necessary for planning land grading were time-consuming, a factor that restricted the alternatives available for final design. Today, computers rapidly explore many possibilities before a final land grading design is selected.

In a subsurface drainage system, often called a tile system, all parts except the outlet are located below the surface of the ground. It provides better drainage than a surface system because it removes water from the soil to the depth of the drain, providing plants a greater mass of soil for root development, permitting the soil to warm up faster in the spring, and maintaining a better balance of bacterial action, the air in the soil, and other factors needed for maximum crop growth.

The smallest component of the subsurface system, the lateral, primarily removes water from the soil. The laterals may be arranged in either a uniform or a random pattern. The choice is governed by the crop grown and its value, the characteristics of the soil, and the precipitation pattern.

Depth of spacing of laterals

The primary decision required for a system with uniform laterals is their depth and spacing. In general, the deeper the laterals can be emplaced, the farther apart they can be spaced for an equivalent degree of drainage. Theoretical studies have shown that laterals can be spaced 24 feet (7.3 metres) apart for each foot of depth. Laterals usually are spaced from 80 to 300 feet (24 to 91 metres) apart and three to five feet (0.9 to 1.5 metres) deep.

Subsurface drainage systems are as important in many irrigated areas as they are in humid areas. A drainage system is needed on irrigated lands to control the water table and ensure that water will be able to move through a soil, thus keeping salts from accumulating in the root zone and making the soil unproductive.

Construction and maintenance. Most subsurface drains are constructed by excavating a trench, installing a tile, and backfilling the trench. Work is in progress in the United States and in Europe to develop machines that will install drain tubes without excavating the trench. Control of the machines to assure proper slope of the drain has been a major problem, but recent development in excavation technology, including the use of laser beams for grade control, have helped to solve it. Traditionally, clay or concrete tile has been the principal material used, but many types of perforated plastic tubes are now employed. An advantage is the reduction in weight of the material handled.

With proper maintenance, drainage systems give relatively long life. Selected herbicides are applied to keep woody growth and water weeds out of the channels. Grates are usually installed over outlets to prevent rodents and burrowing animals from building nests.

Surface drainage systems need almost yearly maintenance to assure the slope and cross section of the channels and the slope of the graded areas because the slopes are so flat that small changes in the ground surface can make marked changes in the ability of a system to function.

Subsurface systems need periodic inspection but usually require little servicing. The outlet of the system and infrequent structural failure of the material are the usual points for service.

LAND RECLAMATION THROUGH IRRIGATION AND DRAINAGE

The need for increased food and fibre production in the 1980s and '90s requires the continued development of new agricultural lands. Development of such land is rarely possible without irrigation or drainage systems or both. Easily recognized improvements are the large-scale river-basin projects designed for flood control, irrigation, and power generation. Such projects are in various stages of design or construction in many countries of the world—for example, the People's Republic of China, India, Egypt, Iran, Australia, and the United States. In almost all cases drainage of the irrigated lands is considered a companion requirement. If possible, the drainage improvements are subsurface.

Reclaiming salty soils

A combination of drainage and irrigation is being used to reclaim large areas of land that have been abandoned because of salt accumulation. In this case subsurface drainage systems must be installed so that high water tables are lowered and pure water flushed through the soil, dissolving the salts and carrying them away in the drainage water. Large areas in the United States, India, and the Middle East are potentially available for reclamation by this technique.

The people of The Netherlands have reclaimed land from the sea by the use of drainage. Since the IJsselmeer (formerly Zuiderzee) barrier dam was closed in 1932, converting this large body of water into a freshwater lake, the Dutch have been continually enclosing and reclaiming smaller bodies (polders). After dikes are built around a polder, the area is drained by pumping out the water. Drainage channels and, in many places, subsurface drains are installed so that the root zone of crops can be drained. After this, cropping is started as the last step in the reclamation process.

The development of land-clearing machinery and surface-drainage techniques has made it possible to clear and drain tropical lands for agricultural production. The first step is the removal of trees, brush, and other tropical growth. Outlet ditches are constructed, followed by drains. In some cases subsurface drains are possible, but more often the soils and rainfall conditions combine to make this improvement impractical. Surface drains are installed on a uniform pattern and the land is smoothed or graded. Drainage systems on newly reclaimed tropical land require special attention while the soils are stabilizing, and some reconstruction is often needed after the soil stabilization is complete.

IRRIGATION AND DRAINAGE THROUGHOUT THE WORLD

The Food and Agriculture Organization of the United Nations (FAO) keeps the most complete statistics on irrigated lands; it estimates that in the entire world some 520,000,000 acres (211,700,000 hectares) are irrigated. FAO data, supplied by each country, indicate that the largest areas under irrigation are located in such countries as the People's Republic of China, India, Pakistan, and the United States. More than 130 countries report some acreage under irrigation. The largest area reported was estimated as 113,700,000 acres (46,000,000 hectares) in the People's Republic of China. Asia, excluding the former Soviet republics, irrigates close to 65 percent of the total area of the world that is irrigated; most of this is the large surface-irrigated, rice-producing areas of the People's Republic of China, India, Pakistan, and Southeast Asia. The United States has approximately 10 percent of the world's irrigated areas. Europe has roughly 7 percent, South America and Africa each about 4 percent, and Central America about 3 percent. Australia and New Zealand together have 1 percent or less. Sprinkler irrigation is employed throughout the world, but the largest acreage to make use of the sprinkler method is the approximately 9,900,000 acres (4,006,500 hectares) in the United States.

Statistics on drainage improvements are sparser than statistics on irrigation. It may safely be said that drainage in one form or another is practiced in almost every country of the world. It is now universally accepted that drainage is needed as much on irrigated as on nonirrigated land. Coantries such as India that have large-scale river-basin developments planned with irrigation also have companion drainage systems planned so that the land will not be damaged by salt accumulation.

U.S. drainage census

Some indication of the world picture may be gained from the drainage census in the United States of 1959, which showed that about 92,000,000 acres (37,200,000 hectares) were drained through organized projects, about 10 percent of the land in agriculture. A rule of thumb states that there is at least one acre of privately drained land for each acre in an organized project, indicating about 185,000,000 acres (75,000,000 hectares) of agricultural land drained in the United States at that time. In the late 1970s about 5 percent of the agricultural land in the United States was drained.

It is almost certain that the land area of the world improved by irrigation and drainage will continue to increase because these practices are two of the most elemental means of reclaiming and improving agricultural lands.

(B.A.J.)

Soil preparation

Mechanical processing of soil so that it is in the proper physical condition for planting is usually referred to as tilling; adding nutrients and trace elements is called fertilizing. Both processes are important in agricultural operations.

TILLING

Tillage is the manipulation of the soil into a desired condition by mechanical means; tools are employed to achieve some desired effect (such as pulverization, cutting, or movement). Soil is tilled to change its structure, to kill weeds, and to manage crop residues. Soil-structure modification is often necessary to facilitate the intake, storage, and transmission of water and to provide a good environment for seeds and roots. Elimination of weeds is important, because they compete for water, nutrients, and light. Crop residues on the surface must be managed in order to provide conditions suitable for seeding and cultivating a crop.

Desirable soil structure

Generally speaking, if the size of the soil aggregates or particles is satisfactory, preparation of the seedbed will consist only of removing weeds and the management of residues. Unfortunately, the practices associated with planting, cultivating, and harvesting usually cause destruction of soil structure. This leaves preparation of the seedbed as the best opportunity to create desirable structure, in which large and stable pores extend from the soil surface to the water table or drains, ensuring rapid infiltration and drainage of excess or free water and promoting aeration of the subsoil. When these large pores are interspersed with small ones, the soil will retain and store moisture also.

Seedbed-preparation procedures depend on soil texture and the desired change in size of aggregates. In soils of coarse texture, tillage will increase aggregate size, provided it is done when only the small pores are just filled with water; tillage at other than this ideal moisture will make for smaller aggregates. By contrast, fine-textured soils form clods; these require breakage into smaller units by weathering or by machines. If too wet or too dry, the power requirements for shattering dry clods or cutting wet ones are prohibitive when using tillage alone. Thus, the farmer usually attempts tillage of such soils only after a slow rain has moistened the clods and made them friable.

Some soils require deepening of the root zone to permit increased rate of water intake and improved storage. Unfavourable aeration in zones of poor drainage also limits root development and inhibits use of water in the subsoil.

Tillage, particularly conventional plowing, may create a hardpan, or plow sole; that is, a compacted layer just below the zone disturbed by tillage. Such layers are more prevalent with increasing levels of mechanization; they reduce crop yields and must be shattered, allowing water to be stored in and below the shattered zone for later crops.

Primary tillage equipment. Equipment used to break and loosen soil for a depth of six to 36 inches (15 to 90 centimetres) may be called primary tillage equipment. It includes moldboard, disk, rotary, chisel, and subsoil plows.

The moldboard plow

The moldboard plow is adapted to the breaking of many soil types. It is well suited for turning under and covering crop residues. There are hundreds of different designs, each intended to function best in performing certain tasks in specified soils. The part that breaks the soil is called the bottom or base; it is composed of the share, the landside, and the moldboard.

When a bottom turns the soil, it cuts a trench, or furrow, throwing to one side a ribbon of soil that is called the furrow slice. When plowing is started in the middle of a strip of land, a furrow is plowed across the field; on the return trip, a furrow slice is lapped over the first slice. This leaves a slightly higher ridge than the second, third, and other slices. The ridge is called a back furrow. When two strips of land are finished, the last furrows cut leave a trench about twice the width of one bottom, called a dead furrow. When land is broken by continuous lapping of furrows, it is called flat broken. If land is broken in alternate back furrows and dead furrows, it is said to be bedded or listed.

Different soils require different-shaped moldboards in order to give the same degree of pulverization of the soil. Thus, moldboards are divided into several different classes, including stubble, general-purpose, general-purpose for clay and stiff-sod soil, slat, blackland, and chilled general-purpose (Figure 7). The blackland bottom is used, for example, in areas in which the soil does not scour easily; that is, where the soil does not leave the surface of the emerging plow clean and polished.

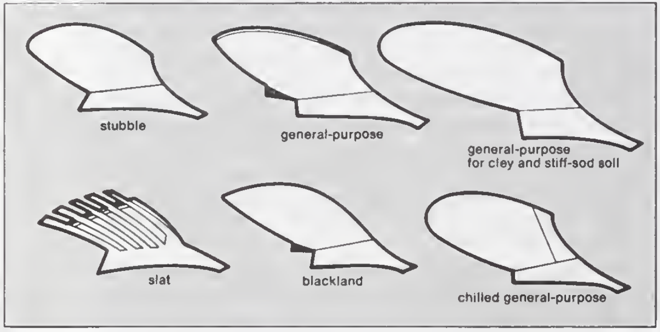

Figure 7: Plow bottom types.

The share is the cutting edge of the moldboard plow. Its configuration is related to soil type, particularly in the down suction, or concavity, of its lower surface. Generally, three degrees of down suction are recognized: regular for light soil, deep for ordinary dry soil, and double-deep for clay and gravelly soils. In addition, the share has horizontal suction, which is the amount its point is bent out of line with the landside. Down suction causes the plow to penetrate to proper depth when pulled forward, while horizontal suction causes the plow to create the desired width of furrow.

Moldboard-plow bottom sizes refer to width between share wing and the landside. Tractor-plow sizes generally range from 10 to 18 inches (25 to 45 centimetres), although larger, special-purpose types exist.

On modern mechanized farms, plow bottoms are connected to tractors either as trailing implements or integrally. One or more bottoms may be so attached (Figure 8). They are found paired right and left occasionally (two-way), with the advantage of throwing the furrow slice in a constant direction as the turns are made. A variation is the middlebreaker, or lister, which is a bottom equipped with both right- and left-handed moldboards.

The disk plow

The disk plow employs round, concave disks of hardened steel, sharpened and sometimes serrated on the edge, with diameters ranging from 20 to 38 inches (50 to 95 centimetres). It reduces friction by making a rolling bottom in place of a sliding one. Its draft is about the same as that of the moldboard plow. The disk plow works to advantage in situations where the moldboard will not, as in sticky nonscouring soils; in fields with a plow sole; in dry, hard ground; in peat soils; and for deep plowing. The disk-plow bottom is usually equipped with a scraper that aids in pulverizing the furrow slice. Disk plows are either trailed or mounted integrally on a tractor.

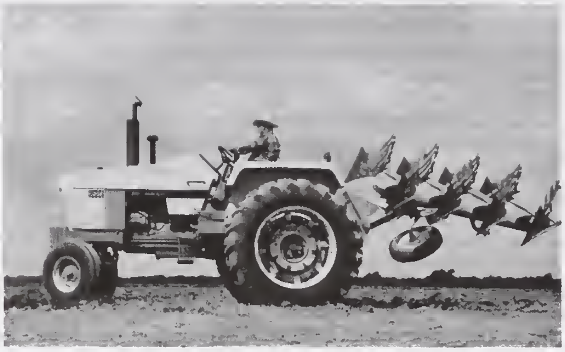

Figure 8: Tractor equipped with integrally mounted four-bottom two-way slat plow.
By courtesy of Robert E Stewart

The rotary plow's essential feature is a set of knives or tines rotated on a shaft by a power source. The knives chop the soil up and throw it against a hood that covers the knife set. These machines can create good seedbeds, but their high cost and extra power requirement have limited general adoption, except for the small garden tractor.

The chisel plow is equipped with narrow, double-ended shovels, or chisel points, mounted on long shanks. These points rip through the soil and stir it but do not invert and pulverize as well as the moldboard and disk plows. The chisel plow is often used to loosen hard, dry soils prior to using regular plows; it is also useful for shattering plow sole.

Subsoil plows are similar in principle but are much larger, since they are used to penetrate soil to depths of 20 to 36 inches (50 to 90 centimetres). Tractors of 60 to 85 horsepower are required to pull a single subsoil point through a hard soil at a depth of 36 inches. These plows are sometimes equipped with a torpedo-shaped attachment for making subsurface drainage channels.

Harrows and pulverizers

Secondary tillage. Secondary tillage, to improve the seedbed by increased soil pulverization, to conserve moisture through destruction of weeds, and to cut up crop residues, is accomplished by use of various types of harrows, rollers, or pulverizers, and tools for mulching and fallowing. Used for stirring the soil at comparatively shallow depths, secondary-tillage equipment is generally employed after the deeper primary-tillage operations; some primary tillage tools, however, are usable for secondary tillage. There are five principal types of harrows: the disk, the spike-tooth, the spring-tooth, the rotary cross-harrow, and the soil surgeon. Rollers, or pulverizers, with V-shaped wheels make a firm and continuous seedbed while crushing clods. These tools often are combined with each other.

When moisture is scarce and control of wind and water erosion necessary, tillage is sometimes carried out in such a way that crop residues are left on the surface. This system is called trash farming, stubble mulch, or subsurface tillage. Principal equipment for subsurface tillage consists of sweeps and rod weeders. Sweeps are V-shaped knives drawn below the surface with cutting planes horizontal. A mounted set of sweeps provided with power lift and depth regulation is often called a field cultivator.

The typical rod weeder consists of a frame with several plowlike beams, each having a bearing at its point. Rods are extended through the bearings, which revolve slowly under power from a drive wheel. The revolving rod runs a few inches below the surface and pulls up vegetative growth; clearance of the growth from the rod is assisted by its rotation. Rod weeders are sometimes attached to chisel plows.

Some control of weeds is obtained by tillage that leaves the middles between crop rows loose and cloddy. When a good seedbed is prepared only in the row, the seeded crop can become established ahead of the weeds. Plowing with the moldboard plow buries the weed seeds, retards their sprouting, and tends to reduce the operations needed to control them. If weed infestations become bad, they can be reduced somewhat by undercutting.

Since rainfall amount and distribution seldom match crop needs, farmers usually prefer tillage methods that encourage soil-moisture storage at times when crops are not growing. From the soil-moisture standpoint, any tillage practice that does not control weeds and result in greater moisture intake and retention during the storage period is probably unnecessary or undesirable.

Minimum tillage. The use of cropping systems with minimal tillage is usually desirable, because intensive tillage tends to break down soil structure. Techniques such as mulching also help prevent raindrops from injuring the surface structure. Excessive tillage leaves the soil susceptible to crusting, impedes water intake, increases runoff, and thus reduces water storage for crop use. Intensive vegetable production in warm climates where three crops per year may be grown on the same land may reduce the soil to a single-grain structure that facilitates surface cementation and poor aeration.

The loosening and granulating actions of plowing may improve soil structure if the plowing is done when the moisture content is optimum; if not so timed, however, plowing can create unfavourable structure. The lifting and inversion of the furrow slice likewise may not always be desirable, because in many cases it is better to leave a trashy surface.

Seeding in narrow slits in sod

The concept of minimum tillage has received much attention. One type of minimum tillage consists in seeding small grain in sod that has been relatively undisturbed. Narrow slits are cut in the sod and seed and fertilizer placed in the breaks thus formed. Soil normally subject to erosion can be planted to grain this way while still retaining the erosion resistance of the sod. The technique has been successful in preparing winter grazing in southeastern portions of the United States. In another type of minimum tillage, the land is broken and planted without further tillage in seedbed preparation. One approach involves breaking the land and planting seeds in the tractor tracks (wheel-track planting); the tractor weight crushes clods and leaves the seed surrounded by firm soil. Another method consists of mounting a planter behind the plow, thus planting without further traffic and leaving a loose seedbed that is satisfactory in areas where postplanting rains may be heavy. In some areas, where winter rain often comes after wheat is drilled, a rotation of wheat following peas has been successful. After the peas have been harvested, the field is rough plowed, and fall wheat is then drilled in directly. All these methods minimize expense and land preparation, tending to leave the soil rough, which reduces erosion and increases water intake. Somewhat similar systems are employed with row crops, where chemical weed control assists in reducing need for cultivation.

Mulch tillage. Mulch tillage has been mentioned already; in this system, crop residues are left on the surface, and subsurface tillage leaves them relatively undisturbed. In dryland areas, a maximum amount of mulch is left on the surface; in more humid regions, however, some of the mulch is buried. Planting is accomplished with disk openers that go through several inches of mulch. Since mulch decomposition may deprive the crop of nitrogen, extra fertilizer is often placed below the mulch in humid areas. In rainy sections, intercropping extends the protection against erosion provided by mulches. Intercrops are typically small grains or sod crops such as alfalfa or clover grown between the rows of a field crop that reach maturity shortly after the field crop has been established and furnish mulch cover for a long time (Figure 9).

Intercropping as protection against erosion

By courtesy of the U S Department of Agriculture

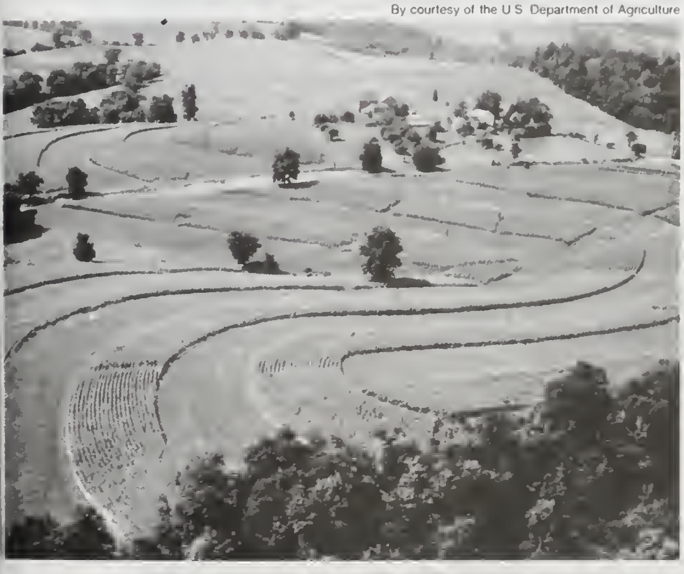

Figure 9: Intercropping to reduce soil erosion, near Fresno, Ohio.

If growth of the intercrop competes with the main crop for moisture and nutrients, that growth may be killed at seeding time or soon thereafter by undercutting with sweeps.

Tillage in dry areas must make maximum use of scanty rainfall. The lister (double-mold board) plow, or middlebreaker, is here used to make water-impounding ridges that promote infiltration. The special problems of dryland farming will be considered below (see *Regional variations: Dryland farming*).

FERTILIZING AND CONDITIONING THE SOIL

Soil fertility is the quality of a soil that enables it to provide compounds in adequate amounts and proper balance to promote growth of plants when other factors (such as light, moisture, temperature, and soil structure) are favourable. Where fertility of a soil is not good, natural or manufactured materials may be added to supply the needed plant nutrients; these are called fertilizers, although the term is generally applied to largely inorganic materials other than lime or gypsum. Fertilizer grade is a conventional expression that indicates the percentage of plant nutrients in a fertilizer; thus, a 10–20–10 grade contains 10 percent nitrogen, 20 percent phosphoric oxide, and 10 percent potash. The green plant, however, requires more nutrients than these.

Essential plant nutrients. In total, the plant has need of at least 16 elements, of which the most important are carbon, hydrogen, oxygen, nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium.

The plant obtains carbon and hydrogen dioxide from the atmosphere; other nutrients are taken up from the soil. Although the plant contains sodium, iodine, and cobalt, these are apparently not essential. This is also true of silicon and aluminum.

Overall chemical analyses indicate that the total supply of nutrients in soils is usually high in comparison with the requirements of crop plants. Much of this potential supply, however, is bound tightly in forms that are not released to crops fast enough to give satisfactory growth. Because of this, the farmer is interested in measuring the available nutrient supply as contrasted to the total quantities. This point will be considered later.

Organic and inorganic soils

The solid content of soils is broadly classified as organic and inorganic. Materials of organic origin range from fresh plant tissue to the more or less stable black or brown degradation product (humus) formed by biological decay. The organic matter is a potential source of nitrogen, phosphorus, and sulfur; it contains more than 95 percent of the total nitrogen, 5 to 60 percent of the total phosphorus, and 10 to 80 percent of the total sulfur. These three elements are cycled through the entire environment of living things (the biosphere). The soil organic matter can be considered as one of the storage points in these cycles. Where nonlegumes are grown in the absence of fertilizer or manures, the crop must gain its nitrogen supply from the organic matter; only a part, however, of the needed phosphorus and sulfur is so supplied.

The inorganic or mineral fraction, which comprises the bulk of most soils, is derived from rocks and their degradation products. The power to supply plant nutrients is much greater in the larger particles, sand and silt, than in the fine particles, or clay. The minerals that comprise the sand and silt in soil contain most of the elements essential for plant growth as a part of their structure. The difficulty is that these minerals decompose so slowly in soil that the rate of supply of the nutrient elements is usually insufficient for good growth of plants.

When the available supply of a given nutrient becomes depleted, its absence becomes a limiting factor in plant growth, and the addition of this nutrient to the soil will increase yields of dry matter. Excessive quantities of some nutrients may cause decrease in yield, however.

Determining nutrient needs. Determination of a crop's nutrient needs is an essential aspect of fertilizer technology. The appearance of a growing crop may indicate need of fertilizer; in some plants, however, the need for more or different nutrients may not be easily observable. If such a problem exists, its nature must be diagnosed, the degree of deficiency must be determined, and the amount and kind of fertilizer needed for a given yield must be found. There is no substitute for detailed examination of plants and soil conditions in the field, followed by simple fertilizer tests, quick tests of plant tissues, and analysis of soils and plants.

Sometimes plants show symptoms of poor nutrition. Chlorosis (general yellow or pale-green colour), for example, indicates lack of sulfur and nitrogen. Iron deficiency produces white or pale-yellow tissue. Symptoms can be misinterpreted, however. Plant disease can produce appearances resembling mineral deficiency, as can various organisms. Drought or improper cultivation or fertilizer application each may create deficiency symptoms.

Strip tests of fertilizer elements

After field diagnosis, the conclusions may be confirmed by experiments in a greenhouse or by making strip tests in the field. In strip tests, the fertilizer elements suspected of being deficient are added, singly or in combination, and the resulting plant growth observed. Next, it is necessary to determine the extent of the deficiency.

An experiment in the field can be conducted by adding nutrients to the crop at various rates. The resulting response of yield in relation to amount of nutrient supplied will indicate the supplying power of the unfertilized soil in terms of bushels or tons of produce. If the increase in yield is large, this practice will show that the soil has too little of a given nutrient. Such field experiments may not be practical, because they can cost too much in time and money. Soil-testing laboratories are available in most areas; they conduct chemical soil tests to estimate the availability of nutrients. Commercial soil-testing kits give results that may be very inaccurate, depending on techniques and interpretation. Actually, the most accurate system consists of laboratory analysis of the nutrient content of plant parts, such as the leaf. The results, when correlated with yield response to fertilizer application in field experiments, can give the best estimate of deficiency. Further development of remote sensing techniques, such as infrared photography, are under study and may ultimately become the most valuable technique for such estimates.

The economics of fertilizers. The practical goal is to determine how much nutrient material to add. Since the farmer wants to know how much profit to expect if he buys extra fertilizer, the tests are interpreted as an estimation of increased crop production that will result from nutrient additions. Cost of nutrients must be balanced against value of crop or even against alternative procedures, such as investing the money in something else with a greater potential return. The law of diminishing returns is well exemplified in fertilizer technology. Past a certain point, equal inputs of chemicals produce less and less yield increase. The goal of the farmer is to use fertilizer in such a way that the most profitable rate is employed.

Fertilizers can aid in making profitable changes in farming. Operators can reduce costs per unit of production and increase the margin of return over total cost by increasing rates of application of fertilizer on principal cash and feed crops. They are then in a position to invest in soil conservation and other improvements that are needed when shifting acreage from surplus crops to other uses.

Farm manure. Among sources of organic matter and plant nutrients, farm manure has been of major importance in past years. Manure is understood to mean the refuse from stables and barnyards, including both excreta and straw or other bedding material, while the term fertilizer refers to chemicals. Large amounts of manure are produced by livestock; such manure has value in maintaining and improving soil because of the plant nutrients, humus, and organic substances contained in it.

As manure must be managed carefully in order to derive the most benefit from it, some farmers may be unwilling to expend the necessary time and effort. Manure must be carefully stored to minimize loss of nutrients, particularly nitrogen. It must be applied to the right kind of crop at the proper time. Also, additional fertilizer may be needed, such as phosphoric oxide, in order to gain full value of the nitrogen and potash that are contained in manure.

Fertilizer value of manure

Manure is fertilizer graded as approximately 0.5–0.25–0.5 (percentages of nitrogen, phosphoric oxide, and potash), with at least two-thirds of the nitrogen in slow-acting forms. Commercial fertilizer equivalent to one ton (900 kilograms) of average manure can be purchased at a fairly low price. Furthermore, the expense of applying 100 pounds (45 kilograms) of 10–5–10 fertilizer is much less than the cost of applying 20 times as much manure. On properly tilled soils, the returns from fertilizer usually will be greater than from an equivalent amount of manure. The application of manure to a crop cannot be controlled as readily as can granulated fertilizer. In general, manure does not provide all the plant nutrients needed and fails to provide any that cannot be supplied by artificial fertilizers. Thus, there is a tendency to discount the value of manure as fertilizer. In underdeveloped countries, however, where artificial fertilizer may be costly or unavailable and where labour is relatively cheap, manure is attractive as a fertilizer.

The main benefits of manure are indirect. It supplies humus, which improves the soil's physical character by increasing its capacity to absorb and store water, by enhancement of aeration, and by favouring the activities of lower organisms. Manure incorporated into the topsoil will help prevent erosion from heavy rain and slow down evaporation of water from the surface. In effect, the value of manure as a mulching material may be greater than is its value as a source of essential plant nutrients.

Green manuring. In reasonably humid areas, the practice of green manuring can improve yield and soil qualities. A green-manure crop is grown and plowed under for its beneficial effects, although during its growth it may be grazed. These green crops are usually annuals, either grasses or legumes, whose roots bear nodule bacteria capable of fixing atmospheric nitrogen. Among the advantages of green-manure crops are the addition of nitrogen to the soil, increase in general fertility level, reduction of erosion, improvement of physical condition, and reduction of nutrient loss from leaching. Disadvantages include the chance of not obtaining a satisfactory growth; the possibility that the cost of growing the manure crop may exceed the cost of applying commercial nitrogen; possible increases in disease, insects, and nematodes (parasitic worms); and possible exhaustion of soil moisture by the crop.

Advantages of green-manure crops

Green-manure crops are usually planted in the fall and turned under in the spring before the summer crop is sown. Their value as a source of nitrogen, particularly that of the legumes, is unquestioned for certain crops such as potatoes, cotton, and corn (maize); for other crops, such as peanuts (groundnuts; themselves legumes), the practice is questionable. Farmers are gradually turning away from growing green-manure crops except where the crop may also serve as winter cover for the land.

Compost, peat, and sludge. Compost, peat, and sludge are used in agriculture and gardening as soil amendments rather than as fertilizers, because they have a low content of plant nutrients. They may be incorporated into the soil or mulched on the surface. Heavy rates of application are common.

Compost, or synthetic manure, is basically a mass of rotted organic matter made from waste-plant residues. Addition of nitrogen during decomposition is usually advisable. The result is a crumbly material that when added to soil does not compete with the crop for nitrogen. When properly prepared, it is free of obnoxious odours. Composts commonly contain about 2 percent nitrogen, 0.5 to 1 percent phosphorus, and about 2 percent potassium; if phosphate and potash are added while composting, those values are higher. The nitrogen of compost becomes available slowly and never approaches that available from inorganic sources. This slow release of nitrogen reduces leaching and extends availability over the whole growing season. Composts are essentially fertilizers with low nutrient content, which explains why large amounts are applied. The maximum benefits of composts on soil structure (better aggregation, pore spacing, and water storage) and on crop yield usually occur after several years of use.

In practical farming, the use of composted plant residues must be compared to the use of fresh residues. More beneficial soil effects usually accrue with less labour by simply turning under fresh residues; also, since one-half the organic matter is lost in composting, fresh residues applied at the same rate will cover twice the area that composted residues would cover. In areas where commercial fertilizers are expensive, labour is cheap, and implements are simple, however, composting meets the needs and is a logical practice.

Peat and peat moss

Peat, composed of prehistoric plant remains that have accumulated under airless conditions in bogs, is a widely used organic soil amendment. Peat moss, the remains of sphagnum plants, is probably its most common form; it contains less than 1 percent nitrogen, with phosphorus and potassium below 0.1 percent. It is highly acid, with pH between 3 and 4.5 (a pH value of 7 is neutral and one above 7 basic). Peat improves the water-storage capability of soils and gives better structure to fine soils. Heavy applications of peat is usually the practice. It is used mostly by specialty-crop producers and on lawns and gardens.

Sewage sludge is the solid material remaining from the treatment of sewage. Its value for soil improvement depends on the method used for treating the sewage. Activated sludge, which results from aerobic (oxygen) treatment, contains 5 to 6 percent nitrogen and 1 to 3.5 percent of phosphorus. After suitable processing, it is sold as fertilizer and soil amendment for use on lawns, parks, and golf courses. It is rarely used in farming.

Liming. Liming to reduce soil acidity is practiced extensively in humid areas where rainfall leaches calcium and magnesium from the soil, thus creating an acid condition. Calcium and magnesium are major plant nutrients supplied by liming materials. Ground limestone is widely used for this purpose; its active agent, calcium carbonate, reacts with the soil to reduce its acidity. The calcium is then available for plant use. The typical limestones, especially dolomitic, contain magnesium carbonate as well, thus also supplying magnesium to the plant.

Another liming material is basic slag, a by-product of steel manufacture; its active ingredient is calcium silicate. Marl and chalk are soft, impure forms of limestone and are sometimes used as liming materials, as are oyster shells. Calcium sulfate (gypsum) and calcium chloride, however, are unsuitable for liming, for, although their calcium is readily soluble, they leave behind a residue that is harmful.

Lime is applied by mixing it uniformly with the surface layer of the soil. It may be applied at any time of the year on land plowed for spring crops or winter grain or on permanent pasture. After application, plowing, disking, or harrowing will mix it with the soil. Such tillage is usually necessary, because calcium migrates slowly downward in most soils. Lime is usually applied by trucks specially equipped and owned by custom operators.

Methods of application. Fertilizers may be added to soil in solid, liquid, or gaseous forms, the choice depending on many factors. Generally, the farmer tries to obtain satisfactory yield at minimum cost in money and labour.

Liquid or solid application of manure

Manure can be applied as a liquid or a solid. When accumulated as a liquid from livestock areas, it may be stored in tanks until needed and then pumped into a distributing machine or into a sprinkler irrigation system. The method reduces labour, but the noxious odours are objectionable. The solid-manure spreader conveys the material to the field, shreds it, and spreads it uniformly over the land. The process can be carried out during convenient times, including winter, but rarely when the crop is growing.

Application of granulated or pelleted solid fertilizer has been aided by improved equipment design. Such devices, depending on design, can deposit fertilizer at the time of planting, side-dress a growing crop, or broadcast the material. Fertilizer attachments are available for most tractor-mounted planters and cultivators and for grain drills and some types of plows. They deposit fertilizer with the seed when planted, without damage to the seed, yet the nutrient is readily available during early growth. Placement of the fertilizer varies according to the types of crops; some crops require banding above the seed, while others are more successful when the fertilizer band is below the seed.

The use of liquid and ammonia fertilizers is growing, particularly of anhydrous ammonia, which is handled as a liquid under pressure but changes to gas when released to atmospheric pressure. Anhydrous ammonia, however, is highly corrosive, inflammable, and rather dangerous if not handled properly; thus, application equipment is quite specialized. Typically, the applicator is a chisel-shaped blade with a pipe mounted on its rear side to conduct the ammonia five to six inches (13 to 15 centimetres) below the surface. Pipes are fed from a pressure tank mounted above. Mixed liquid fertilizers containing nitrogen, phosphorus, and potassium may be applied directly to the surface—by field sprayers where close-growing crops are raised. Large areas can be covered rapidly by use of aircraft, which can distribute both liquid and dry fertilizer.

The future for fertilizers. Future trends in fertilizer technology may be predicted by extrapolating from current developments. Mixtures and materials with high percentages of plant nutrients will dominate the field. Better ways of providing nitrogen, the most expensive of the three major nutrients, will be forthcoming, including increased use of anhydrous ammonia, ammonium nitrate, and urea. Nonleachable nitrogen, for example, can be obtained through the urea–formaldehyde (ureaform) reaction, and ammonium metaphosphate offers a concentrated liquid product. Micronutrients, or trace elements, specific to particular geographical areas will come into increasing use, as will custom mixing and bulk selling of mixtures containing several nutrients based on reliable soil and plant data.

New methods of providing nitrogen

"Complete environment" seeding in which seed, fertilizer, and water are incorporated in a biodegradable (decomposable in the soil) tape may come into use; with the tape planted, no further fertilizer or water will be needed until growth is well established. Such techniques using biodegradable tapes have already been developed on a small scale for use by home gardeners. Finally, larger and more precise fertilizing machines will be developed and adopted.

Factors in cropping

CROPPING SYSTEMS

The kind and sequence of crops grown over a period of time on a given area of soil can be described as the cropping system. It may be a pattern of regular rotation of different crops or one of growing only one crop year after year on the same area.

Crop rotation. Early agricultural experiments showed the value of crop rotations that included a legume sod crop in the regular sequence. Such a system generally maintains productivity, aids in keeping soil structure favourable, and tends to reduce erosion. Alfalfa, sweet clover, red clover, and Ladino clover are considered effective for building up nitrogen. Some legumes, however, do not leave nitrogen behind in the soil because it is deposited as protein in the harvested seed; soybeans are an example. Turning under the top growth of a legume aids in adding nitrogen. Though yields of grains are higher when they are rotated with legumes, it is difficult to determine how much of the improvement depends on the nitrogen added by the legume and how much on improved soil structure or fewer insects and disease.

The determination of the best rotation depends upon whether the crops compete with each other (*i.e.*, if growing one crop lowers the yield of its successor) or complement each other; and the output of one crop on a given acreage leads to increased output of the other. This desirable complementary relationship exists only when one crop or soil-management practice concurrent with it provides nutrient or conditions required by the other crop. In this circumstance, grasses and legumes may complement grains or row crops by furnishing nitrogen, controlling erosion and pests, and improving soil structure to such an extent that greater production is achieved. The reverse can also occur; in certain prairie soils, continuous growing of deep-rooted legumes depletes soil moisture, and subsequent forage yield is improved by frequent plowing of the sod and planting of corn. In high-rainfall or irrigated areas, forage stands deteriorate from winter killing, disease, or grazing, to a point where a year of grain in the rotation allows an improved stand of forage later. Fallow (idle) land is complementary to wheat and other small grains in subhumid areas such as the Great Plains of the United States; such rotation is quite beneficial to wheat yield. Complementary relationships between crops can be terminated by the application of the physical law of diminishing returns, however, and give way to competition.

Rotation as a benefit to wheat yield

Both long-range and short-range profits motivate the farmer as cropping systems are examined in relationship to soil erosion. Excessive loss of soil to streams, rivers, and reservoirs is unacceptable to public policy as well as economically damaging to the farmer, and crop rotations that promote erosion are minimized. Soil losses are least from fields in continuous sod and most from continuous row crops. If row crops are grown in rotation with sod, the erosive susceptibility of row crops is reduced over a period of time. Peanuts (groundnuts), potatoes, tobacco, cotton, sugar beets, and some vegetables, and similar row crops that require frequent cultivation (intertillage) and leave minimal post-harvest residue are most likely to permit serious erosion. Less erosive are row crops such as corn (maize), sugarcane, and grain sorghum, which require less cultivation and leave more residue. Small grains such as wheat, oats, barley, and rye usually permit less erosion than the row crops. Among sod crops, grasses or grass–legume mixtures are less erosive than pure stands of legumes such as alfalfa. Fortunately, cropping systems that tend to control soil erosion usually tend also to give better yields than systems that promote excessive erosion. This results from increased availability of water to the plants and increased amounts of nutrients, which in erosive systems are washed away and lost.

Monoculture. The practice of growing the same crop each year on a given acreage, monoculture, has not been generally successful in the past, because nonlegume crops usually exhaust the nitrogen in the soil, with a resulting reduction in yields; this is particularly true in humid regions. The advent of low-cost nitrogen fertilizers, however, has induced reconsideration of the possible advantages of monoculture. These advantages can best be discussed in terms of a hypothetical general farm where it may be desirable to produce several different kinds of crops: the question to be answered is whether monoculture can do better than rotational systems in producing these crops while still maintaining productivity.

Advantages of monoculture. First, if different kinds of soil exist on the farm, a monoculture system may permit each crop to be grown on the soil best suited to it. Forage crops, for example, could be confined to steep land to minimize erosion; intertilled crops could be planted on the better soils with gentle slopes. Wet areas could be used continuously for crops not requiring early-spring field operations, while dry soils could be used for drought-resistant crops such as sorghums or winter small grains.

Second, the fertility level of the soil can be adjusted to fit one crop more precisely than it can be adjusted to fit all the crops in a rotation.

Third, where continuous cropping is practiced and perennial forage crops are used, regular reseedings are avoided. This is an advantage, because each seeding is accompanied by the possibility of failure.

Flexibility in monoculture crop planning

Fourth, systems based on monoculture usually offer greater flexibility in planning the system to meet year to year changes in the need for various crops. Part of the acreage can be shifted from one crop to another without upsetting the total farm cropping plan.

Disadvantages of monoculture. On the other hand, requirements for successful monoculture are more demanding of management skill than are sod-based rotations. The entire nitrogen need of nonlegume crops must be met by purchased fertilizers or by use of manure. Closer attention to soil erosion is necessary, except for perennial sod. Soil-structure problems can become severe where intertilled crops are grown continuously. In monoculture, the farmer is completely dependent on chemical insecticides, disease-resistant plant varieties, soil fumigation, and similar methods of controlling insects and diseases that are usually controlled by crop rotation.

Thus, the choices of cropping systems that maintain good productivity, minimize soil losses, and are in harmony with demand and desired business organization are not easily made. The growing use of systems analysis will undoubtedly aid in rational selection among the bewildering array of possibilities.

CROP PROTECTION

Crops are vulnerable to attack, damage, and competition. Insects, plant disease, nematodes, rodents, weeds, and air pollution are among the many enemies that can reduce crop yields and deny man the use of some of his farm-stored crops.

Insects, for example, can destroy a crop in a relatively short time. Control measures for many years have engaged the attention of farmer and scientist, yet full success has not been achieved, and the battle continues. The problem is further complicated by the fact that control measures not only kill unwanted insects, but also may harm honey bees as well as the parasites and predators that destroy insect pests.

At least 10,000 species of insects are classed as unwanted. Of these, several hundred species are particularly destructive and require some degree of control. They destroy food as well as the forage, pasture, and grain needed to produce livestock; and, in addition, they carry and transmit many diseases of plants and animals.

Adverse effects of some insecticides

Chemical control of insects. Insecticides generally are effective, cheap, and safe if handled correctly; the good derived from them, however, can be partly offset by adverse effects. Chlorinated hydrocarbon insecticides such as DDT, for example, may leave residues toxic to beneficial insects, fish, and other wildlife; the insecticides may be found in meat and milk, or they may persist in the soil. Another problem is that some species of insects build up resistance to chlorinated hydrocarbon, organic phosphate, and carbamate insecticides. These disadvantages can be overcome only by persistent search for new and safer insecticides accompanied by wide use of nonchemical insect control.

A wide range of organophosphate and carbamate materials is now available. These can be applied to avoid most of the problems related to residues. Malathion and carbaryl, for example, are used to control insects in areas where persistent materials might appear later in meat or milk and can also be applied in areas where fish and wildlife might be affected. Those two chemicals offer a broad range of toxicity to insect pests. Unlike chlorinated hydrocarbons, they can be applied up to within a day or so of harvest without harm to many crops; they are dangerous, however, to those who apply them and must be handled with care.

Some insecticides are effective in very small amounts. This fact has stimulated development of ultralow-volume technology, where special equipment permits dispersal of low volumes of undiluted chemicals, which offers cost advantages as well as drastic reduction of the chemicals in the environment. For example, six to 16 ounces (170 to 450 grams) per acre of Malathion may be effective against grasshoppers, boll weevil, cereal-leaf beetle (*Oulema melanopus*), mosquitoes, and the beet leafhopper (*Circulifer tenellus*). Formulation of chemicals in granules rather than sprays offers some advantages in use and applications; among others, it reduces the amount needed and also lessens the chance of adverse effects on beneficial insects and wildlife.

Systemic insecticides

Certain insects that attack cotton, vegetables, and forage crops may be controlled by chemicals absorbed by the plant. Called systemics, they are placed with the seed at planting time. The chemical is taken up by the plant, and insects die when they attempt to feed on the leaf or stem. Beneficial insects that do not feed on the plant remain unharmed.

Nonchemical control of insects. *Mechanical and cultural controls.* Light traps that give off radiation that attracts insects have been under test for many years. They have been somewhat successful in controlling the codling moth (*Carpocapsa pomonella*) and the tobacco hornworm (*Protoparce sexta*).

Use of reflective aluminum strips, placed like a mulch in vegetable fields, has reduced or prevented aphid attack and thus protected cucumbers, squash, and watermelons from mosaic diseases. This technique may supplant insecticides, which frequently do not kill aphids quickly enough to prevent crop losses from virus transmitted by them.

For stored products, heat or cold can control many insects that frequent such places. Also, changing the proportions of oxygen, nitrogen, and carbon dioxide in the storage atmosphere can provide control.

Recently, it was discovered that, if adult Indian-meal moths (*Plodia interpunctella*) were exposed to certain wavelengths of sound during the egg-laying period, their reproduction was reduced by 75 percent. The sound waves had a similar effect on flour beetles (*Tribolium* species). Further development is needed, but this method offers potential as a nonchemical control. Other types of physical energy can also kill insects. Light waves, high-frequency electric fields, high-intensity radio frequencies, and gamma radiation have been investigated; some offer promise.

Certain cultural practices can prevent or reduce insect crop damage. These include destruction of crop residues, deep plowing, crop rotation, use of fertilizers, strip-cropping, irrigation, and scheduled planting operations. Such practices are useful but cannot be relied upon entirely to eliminate severe infestations.

Biological controls. The question of using biological controls has always been of considerable public interest. The control agents include parasites, predators, diseases, protozoa, and nematodes that attack the insect pests. Biological controls cannot replace insecticides entirely, because nature provides for survival of both beneficial and destructive insects. Before the population of a parasite or predator can expand, a high population of the host species must also be present. Sometimes the control agents are far outnumbered by the pest insect. Parasites and predators have funished good control of the Japanese beetle (*Popillia japonica*), European corn borer (*Pyrausta nubilalis*), alfalfa aphid (*Therioaphis maculata*), alfalfa weevil (*Hypera postica*), and several others.

Microbial agents as controls

Microbial agents can be used for control. There exist about 1,100 viruses, bacteria, fungi, protozoa, rickettsiae, and nematodes that parasitize insects. Many pathogens are specific to a particular insect but are harmless to man and domestic animals. It is a possibility that insect pathogens can be produced, packaged, distributed, and applied in much the same way as insecticides.

The ideal solution to insect-control problems is to plant crop varieties that are resistant to attack. The only difficulty is that such varieties are not universally available, and development entails a very long process.

Sterilization of male insects by gamma radiation and their release into a population of wild insects is a promising approach. It has proved successful in control of screwworms and fruit flies, replacing chemicals in some areas. Chemical attractants, which lure insects into contact with small amounts of insecticide or a sterilant, also offer much promise.

All aspects of insect control considered, it is possible that "integrated control," coordinated employment of more than one method, may be the answer. Combining resistant varieties with a systemic insecticide that leaves the parasites and predators unharmed, for example, has been successful in combatting the spotted alfalfa aphid in California. Preliminary reduction of heavy infestation by chemical spray combined with bait, followed by the sterile-insect technique, provides another example of integrated control. Use of sex attractant in light traps, plus special management of postharvest residues, has controlled the tobacco hornworm. Other examples might be cited, but the principal value of such control methods lies in using less insecticide and thus contributing to maintenance of a good environment.

Control of plant diseases and nematodes. Insects, of course, are not the only agents hazardous to crops. Plant diseases and the microscopic worms called nematodes have the potential of creating wholesale destruction of crops, especially those grown in regions of wide weather fluctuation. In fact, these plant pests sometimes limit the kinds and varieties of crops that can be grown. The damage they cause may sometimes be mistaken for that caused by unfavourable weather. Epidemics may destroy crops completely.

As with insects, control of plant diseases and nematodes covers a broad spectrum of measures: use of chemicals, resistant varieties, quarantine, forecasting and warning, cultural practices, heat treatment, and others. Furthermore, most plant virus diseases are transmitted by insect carriers, so control of insects is linked to control of disease.

Nematodes and plant disease can at times be controlled fairly well by crop rotation, deep plowing, and burning of stubble and debris that remain after harvest. Though burning destroys aboveground organisms and permits economical control by chemicals, it contributes to air pollution and destroys organic matter. In another technique, propane-gas flame is applied to living plants as well as stubble to kill disease spores. A virus disease of sugarcane is controlled by heating diseased cuttings in hot-air ovens. Stem rot disease of peanuts (groundnuts) can be controlled by plowing under dead plant debris or by planting the seed on a raised bed followed by application of a pre-emergence weed killer.

Predicting plant epidemics

Successful control of epidemic plant disease may depend on prompt application of chemicals before the disease outbreak. Many governments operate plant-disease forecasting and warning services for farmers. The service is based primarily on analysis of temperature, rainfall, humidity, and dew—all factors that can create conditions favourable to disease outbreaks.

Weed control. Weed control is vital to agriculture, because weeds decrease yields, increase production costs, interfere with harvest, and lower product quality. Weeds also impede irrigation water-flow, interfere with pesticide application, and harbour disease organisms.

Early methods of weed control included mowing, flooding, cultivating, smothering, burning, and crop rotation. Though these methods are still important, other means are perhaps more typical today, particularly the use of herbicide (plant-killing) chemicals. Another technique is to introduce insects that attack only the unwanted plant and destroy it while leaving the crop plants unharmed.

The inadequacy of the cultural, mechanical, and biological control systems, however, stimulated the rapid development of chemical usage since World War II. Herbicides have had an impact on crop production, changing many cultural and mechanical agricultural operations.

Herbicides are formulated as wettable powders, granular materials, emulsions, and solutions. Any of them may be applied as a spot treatment, broadcast, placed in bands, or put directly on a specific plant part. When formulated as solutions or emulsions, the chemical is mixed with water or oil.

Spraying is the most common method, permitting extremely small amounts to be applied uniformly because of dilution. Sprays can be accurately directed underneath growing plants, and calibration and rate control are easier with spray machines than with granular applicators. Granular formulations have advantages under some conditions, however. The use of herbicides must be integrated into the overall farm program because the optimum date and application rate depend on the crop stage, the weed stage, weather conditions, and other factors.

Careful use of herbicides in farm production lowers cost, resulting in a more economical product for the consumer. Herbicides cut the costs of raising cotton, for example, by reducing labour requirements for weed control up to 60 percent. Herbicides replace hand labour in growing crops, labour that is no longer available in developed nations at costs the farmer can afford. Machines for chemical application are widely available.

Safety of herbicides

When used as directed, herbicides are generally safe, not only for the operator but also for wildlife and livestock.

The greatest difficulty lies in accidental injury to crop plants resulting from drift and from residues in the soil, particularily if residues enter water courses.

The future of chemical pesticides and herbicides is under debate by those who manufacture, sell, and use them and by those who are concerned about environmental quality. The value of an assured food and fibre supply at reasonable cost is undeniable, and chemicals contribute much toward this. These substances also cause undesirable effects upon the environment, however, and indeed can be toxic to a wide range of organisms. This fact will demand an increasing amount of care in using chemicals, perhaps enforced by law, along with increasing use of nonchemical control techniques.

Harvesting and crop processing

HARVESTING MACHINERY

Reaping and threshing processes

Harvesting machinery is generally classified by crop: reapers for cutting cereal grains and threshers for separating the seed from the plant. The more modern combine cuts, threshes, and cleans the grain in one operation. Corn (maize) harvesting is performed by mechanical corn pickers that snap the ears from the stalk so that only the grain and cobs are harvested. Corn shelling may be done mechanically in the field, after or with picking. Stripper-type cotton harvesters, which strip the entire plant of both open and unopened bolls, work best late in the season after frost has killed the green vegetative growth. Hay and forage machines include mowers, crushers, windrowers, field choppers, balers, and some machines that press the hay into wafers or pellets.

Grass, legumes, corn (maize), and other crops are often put into silos to keep them in a succulent and fermented state rather than stored dry as hay. To make silage, the crops must be cut up to permit tight packing in the silo, producing anaerobic fermentation and preventing formation of mold. Almost all silage crops are cut in the field with a forage harvester that cuts and chops the crop immediately or picks up and chops a windrow that has been cut and raked earlier.

Root crops are harvested with diggers and digger-pickers, which often pull up clods, stones, and vines with the crop. Though some machines carry workers who manually sort out extraneous material, this task is increasingly being performed mechanically. Modern sugar-beet harvesters lift the whole root from the ground, clean the earth from it, and deliver it to a bin or wagon. Sometimes the beet tops are removed before harvest of the roots and used for cattle feed. Peanuts (groundnuts) are lifted, vines and all, and allowed to dry before removal of the pods.

Three types of tobacco harvest methods

Tobacco-harvesting aids may be classified in three principal ways, according to the harvesting and curing methods used, which depend on the type of tobacco and its use. Flue-cured tobacco, a large plant that may stand three to four feet (90 to 120 centimetres) high, is harvested with machines that carry several workers who ride the lower platforms of the machines, cut the leaves, and place them on conveyor belts, where the leaves are tied mechanically or by hand. Burley tobacco has usually been harvested by workers using a machete-type knife. After cutting, the large end of the stalk is fixed onto the sharpened end of a stick, which—when loaded with a number of stalks—is hung by hand in a tobacco barn for curing. Researchers are attempting to mechanize the cutting, impaling, and hanging of burley tobacco. Little has been done, however, toward the mechanization of the harvesting of the small aromatic tobacco leaves, which are grown in the shade, picked by hand, tied with a string, then hung for curing.

Tree-crop harvesting, accomplished by hand or with mechanical shakers, is described below under *Fruit farming*. Vegetable crops such as asparagus, lettuce, and cabbage are still harvested largely by hand, though scarcity and high cost of field labour has led to some mechanization in this area, notably with tomatoes.

CROP-PROCESSING MACHINERY

Machinery is widely used to prepare crops for convenient transportation, for safe storage, for the market, and for feeding to livestock. Advances in such machines have been rapid, particularly with new crops, increased yields, multiple-crop practices, and changing techniques.

In the most common method of crop drying, the crop, usually grain, is spread on floors or mats and stirred frequently while exposed to the sun. Such systems, though extremely common in the underdeveloped countries, are very slow and dependent on the weather. Forced-air-drying systems allow the farmer much more freedom in choosing grain varieties and harvest time. Fairly simple in operation, these systems have been gaining popularity in the tropics. Heat is often added to increase air temperatures during the drying period.

Dryeration of corn

In a process called dryeration, wet corn (maize) is placed in a batch or continuous dryer. After losing 10 to 12 percent of its moisture, the hot corn is transferred to the dryeration cooling bin, in which it is tempered for six to 10 hours and then slowly cooled by ventilation for 10 hours. This process reduces kernel damage and increases dryer output.

High moisture in stored hay not only causes rapid deterioration of its value as feed but often results in spontaneous combustion. When hay is first cut, it usually contains 70 percent or more moisture. It wilts and quickly dries to a moisture content of about 40 percent. At this stage, it can be dried to a safe storage condition, about 15 percent moisture, by blowing air through it, sometimes with supplemental heat.

Feed-processing mills, often referred to as feed grinders, are used principally for milling cereals for livestock feed, which aids digestion. The ground material is usually fairly coarse and at times may only be crushed. Modern mills frequently are designed to allow the farmer to grind the grain and to mix in various other ingredients in desired quantities.

Other types of crop-processing machinery include machines that separate desirable seed from weed seed, stems and leaves, and dirt; grading machinery to classify seed by width, length, or thickness; fruit graders and separators; and cotton gins, which separate cotton seeds from the fibres.

Regional variations in technique

DRYLAND FARMING

Dryland-farming crops

Dryland farming refers to production of crops without irrigation in regions where annual precipitation is less than 20 inches (500 millimetres). Where rainfall is less than 15 inches (400 millimetres) per year, winter wheat is the most favoured crop, although spring wheat is planted in some areas where severe winter killing may occur. (Grain sorghum is another crop grown in these areas.) Where some summer rainfall occurs, dry beans are an important crop. All dryland crop yield is mainly dependent on precipitation, but practices of soil management exert great influence on moisture availability and nutrient supply.

Where rainfall exceeds 15 inches (380 millimetres), the variety of crop possibilities is increased. In areas of favourable soils and moisture, seed alfalfa is grown, as is barley. Some grass seed may be grown, particularly crested wheat grass of various types.

Fallow system and tillage techniques. Dryland farming is made possible mainly by the fallow system of farming, a practice dating from ancient times. Basically, the term fallow refers to land that is plowed and tilled but left unseeded during a growing season. The practice of alternating wheat and fallow assumes that by clean cultivation the moisture received during the fallow period is stored for use during the crop season. Available soil nitrogen increases and weeds are controlled during the fallow period. One risk lies in the exposure of soil while fallow, leaving it susceptible to wind and water erosion. Modern power machinery has tended to reduce this risk.

Procedures and kinds of tillage that are comparatively new have proved effective in controlling erosion and improving water intake. Moldboard and disk plows are being replaced with chisels, sweeps, and other tools that stir and loosen the soil but leave the straw on the surface. Where the amount of straw or residue remaining from the previous crop is not excessive, this trashy fallow system works well, and tillage implements are designed to increase its effectiveness.

Contour tillage helps to prevent excessive runoff on moderate slopes. Broad terraces can aid in such moisture conservation. Steeper slopes are planted to permanent cover.

Improving storage of moisture

Compacted zones at a depth of five to eight inches (13 to 20 centimetres) can be caused by tillage. As such zones interfere with storage of moisture, they can be controlled by growing deep-rooted alfalfa at intervals, or the compacted zone can be broken by fall tillage with chisels or sweeps set to a depth just below the zone of compaction. Such deep tillage will result in reduced runoff and deeper moisture penetration.

When using power machinery in dryland farming, the timing of operations is important. The soil is broken in the fall or early spring before weeds or volunteer grain can deplete the moisture. Use of a rod weeder or similar equipment during fallow can control the weeds. Planting is timed to occur during the short period in fall or spring when temperature and moisture are favourable.

Fertilizer use. Fertilizer is an important component of dryland technology. For example, 20 pounds per acre (22 kilograms per hectare) of nitrogen are recommended where rainfall is less than 13 inches (330 millimetres), ranging up to 60 pounds per acre (67 kilograms per hectare) where more rain is available; those figures refer to the production of wheat, but they are applicable to other dryland-farming areas. Where average annual precipitation is less than 12 inches (300 millimetres), the use of nitrogen is limited to years where moisture outlook is exceptionally favourable. Nitrogen fertilizer can be applied either in fall or spring. Band placement or broadcast techniques are utilized. Good results are obtained from broadcast spring application of nitrate fertilizer, and fall application of ammonia has also been successful. Local climates and rainfall patterns also determine choice of fertilizer and time of application.

Crops and planting methods. Alfalfa grown for seed on drylands is planted in rows, usually two to three feet (60 to 90 centimetres) apart; cultivation between rows is required during the first year. Alfalfa is also grown for forage where favourable. This practice builds nitrogen and organic matter, while improving soil structure. These legumes can be rotated with wheat if rain is between 16 and 18 inches (400 and 450 millimetres) and will increase the yield of wheat.

Other crops, such as cotton, peanuts (groundnuts), and grain sorghum, can be grown successfully in dryland agriculture. Where those crops are produced on sandy soils, special techniques are necessary to reduce soil blowing and drifting. Cotton and peanuts do not produce sufficient crop residues for protection from wind erosion, while sorghum does. For this reason, many farmers in such areas use various row combinations of cotton or peanuts with grain sorghum; two rows of grain sorghum and four to eight rows of peanuts in alternating strips is a popular technique. Another is to use a two-year rotation of cotton and grain sorghum, in which two rows are cropped and two rows are fallow. These systems not only afford protection from wind erosion but also promote effective use of soil moisture.

TROPICAL FARMING

The area of the world bounded roughly on the north by the Tropic of Cancer and on the south by the Tropic of Capricorn, a vast land that embraces large parts of Latin America, Africa, India, Australia, and Southeast Asia, contains climates less favourable to agriculture and human settlement than those of the temperate zones. Within this Equator-centred area occur the climates known as tropical, which are characterized by two general types: warm and wet, and warm with partly deficient rainfall. In either, the total precipitation is usually quite heavy, which leaches the tropical soils of nutrients. The area also has high temperatures with little variation the year round. The combination of high temperature and high rainfall causes organic matter to decompose quickly, leaving the soil deficient in humus. Vegetation flourishes in the tropics, along with weeds, insects, and disease organisms. Important climatic variations occur, depending upon land elevation.

Characteristics of tropical areas

Tropical crops include coconut, palm oil, rice, sugar, pineapple, sisal, cocoa, tea, coffee, jute, rubber, pepper, banana, and many others. In certain highland tropical areas, however, the crops common to temperate-climate agriculture can also be grown. The amount of tropical land well-suited to agriculture, however, is limited.

Plant-pest problems. The abundance of plant pests in the tropics, including weeds and disease, makes agriculture successful mainly in the plantation system, where needed control measures can be financed. The alternative is to move from deteriorated land to newer fields; this practice of shifting agriculture has also been common, because tropical soils lose their productive capacity so rapidly. The practice probably cannot be continued indefinitely, however, because of increasing population pressure.

The largest quantities of commercial tropical products originate in plantations, where skilled management is combined with sufficient capital to provide mechanized equipment. This is particularly true in the production of coffee, cocoa, rubber, coconut, banana, pineapple, sugarcane, and others. Much rice is produced in the Asian tropics and Indonesia, however, on small farms with intensive hand labour and simple tools, where the prime mover is likely to be the ox or the water buffalo, not the tractor.

Guyana's system of coastal water control

Water management. Drainage, irrigation, and other special techniques of water management are important in tropical agriculture. An example is the cultivation of rice and sugarcane in the fertile coastal areas of Guyana. Originally through private enterprise and later by government efforts, large coastal areas were "empoldered" (diked) to keep back the sea in front and floods from the rivers in the rear. With a mean annual rainfall of 90 inches (2,300 millimetres), drainage is a critical factor; in fact, the system cannot discharge all possible floodwater, and so the crops must tolerate occasional drowning. With gravity drainage effective only at low tide, the drainage gates are opened on the ebbing tide and closed on the rising tide. Great difficulty is encountered in keeping the outlets unclogged by the heavy sediment discharge. Since rain does not always fall when it is needed, many fields are irrigated. Most of the rice soil is specially tilled after plowing in order to create a better seedbed under the water, using tractors operating in water four to six inches (10 to 15 centimetres) deep. After this special tillage, the seeds are broadcast in one to two inches (2.5 to five centimetres) of water. Though maintenance and operation of such an intricate water-control system are not simple, Guyana rice production has been doubled through its use.

Mechanical problems. Mechanization faces many obstacles before wide adoption is possible in tropical regions. Difficult soils, stones, stumps, abundant labour, resistance from farmers, lack of incentives, lack of skills, lack of capital, low wages, high cost of machines, lack of dealer service, fragmented land ownership, all contribute to slow development of mechanization. Tropical soils differ markedly from those in the countries that manufacture land-preparation machinery, making adaptation of new design necessary. The encountering of stones, wood, trash, and termite mounds causes machines to break down. Depressing climatic conditions reduce the performance of the machine operators. Tropical farm regions are notoriously irregular or mountainous, impeding intensive machine culture. The best soils in Brazil require special erosion controls, reducing the potential for large-scale mechanization. One of the greatest overall impediments to mechanization is the fear that unemployment might result from it, a failure to understand that economic development and higher living standards depend partly on increasing the productivity of labour.

Mechanization in Trinidad

As an example of the problems encountered in mechanizing tropical crops, the harvesting experience of a large sugarcane plantation in Trinidad is illuminating. On flatland of some 30,000 acres (12,000 hectares), the cane is grown on heavy clay soil in a climate with 50 inches (1,300 millimetres) of rain during the seven-month wet season and 10 inches during the five-month dry season. By 1960 the rising wage rate made harvest mechanization imperative. First, the traditional "bed" system, which functioned to remove floodwater, was changed to ridge planting; this made it possible for machines to operate and was a remarkable change in itself. Then it was decided to harvest with the cane combine, which tops, cuts, chops, and loads the chopped cane into transport vehicles. Although the combine is complicated and requires considerable power, it was deemed better than mechanical half-measures.

By 1969 the combines, however, were harvesting only 12.8 percent of the flatland crop, indicating that mechanization was far from complete. Three factors were responsible: first, the cane combines required extensive maintenance plus very expensive replacement parts. Second, it was difficult to mobilize a transport system to receive the output of the combines with any degree of economy. Third, the social problem of displaced workers had to be considered. The combines increased labour productivity sixfold over hand harvesting; thus, their introduction had to be slowed until surplus workers could be accommodated elsewhere. The limited success of this mechanization project indicates how complicated such a process really is.

Taking the largest view of possibilities for improving tropical agriculture, the most promising inputs of technology are improved crop varieties and increased use of fertilizers.

OTHER SPECIALIZED TECHNIQUES

Hydroponics. The term hydroponics denotes soilless culture of plants. The possibilities of this technique have received considerable attention in recent years. In hydroponics, an outgrowth of laboratory techniques long used by scientists, plants are grown with their roots immersed in a water solution containing necessary minerals or rooted in a sand medium kept moistened by such a solution. Soilless culture of plants is similar in principle but larger in scale. A typical hydroponics technique has plants supported in a bed of peat, wood fibre, or similar material, on a wire screen with the roots dipping into the solution below. Aeration of the solution is provided. In another method, the plants are rooted in a medium of sand or gravel contained in a shallow tank into which the solution is pumped at intervals by automatic control. Between pumpings, the solution drains slowly down into a reservoir tank. Hydroponic techniques are practiced on a small scale both out-of-doors and in greenhouses.

Of the elements known to be necessary for plant growth, carbon, oxygen, and hydrogen are obtained by the plant from atmospheric gases or from soil water. The others are all obtained as mineral salts from the soil. The elements absorbed as salts—iron, manganese, boron, copper, zinc, and molybdenum—are required in minute quantities and are called the micronutrients. The principal elements that must be provided as dissolved salts in hydroponic techniques are nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium. Numerous solutions have been devised to fulfill these requirements.

Crop yields of some plants can be obtained fully equal to those obtained on fertile soils. Wide-scale crop production by hydroponics, however, would be economic only for certain intensive types of agriculture or under special conditions. Some greenhouse crops, both vegetables and flowers, are grown by this method. In regions having no soil or extemely infertile soil but with favourable climate, hydroponic techniques have been very useful; for example, on some of the coral islands of the Pacific.

Greenhouses. The greenhouse is typically a structure whose roof and sides are transparent or translucent, permitting a sufficient quality and quantity of solar radiation to enter the structure for photosynthesis (see below). It allows the growing of crops independently of the outside climate, since its interior temperature and humidity can be controlled. Greenhouses vary in size and complexity from small home or hobby structures to large commercial units covering an acre or more of land. An even smaller greenhouse might be termed the hot bed, a glass-topped box containing fermenting organic matter; the fermentation process yields heat, allowing the gardener to start plants from seed in early spring for later transplanting.

The basic construction of a greenhouse consists of a light but sturdy frame capable of resisting winds and other loads. Conventional foundations usually support vertical walls; the roof may be gabled, trussed, or arched. The conventional greenhouse is fitted with glass panes, but plastic-film or fibre-glass panels often supplant glass.

Basic greenhouse construction

Maintenance of temperature within the greenhouse is difficult because of fluctuating outside conditions. When the sun shines brightly, little heat is needed, and the heating system must be controlled in some way to prevent injury to the crop. Hot water, steam, electric cable, or warm-air furnaces provide the heat, which is usually controlled by thermostat. Temperatures in greenhouses are regulated to suit the crop. Typical ranges are from 40° F (4° C) for lettuce, violets, carnations, and sweet peas to 70° F (21° C) for cucumbers, tomatoes, and orchids.

Cooling is often required during summer days in warm climates. Ventilation is the simplest technique, reducing inside temperature to near that of the outdoors. Additional cooling by refrigeration may be required; in dry regions, the evaporative cooler is efficient and also increases the relative humidity within the structure. Another form of environmental control consists of adding extra carbon dioxide to the air if the crop requires it for extra photosynthetic efficiency.

The commercial-greenhouse operator usually grows vegetables or ornamental plants. Such production makes more demands on the grower, because he must assume many of the tasks normally handled by nature in the open fields. He must regulate the temperature, ventilate, adjust the amount of entering sunlight, provide soil moisture, fertilize, and even facilitate pollination. During the off-season, the structure must be cleaned and fumigated, its soil restructured, and mechanical equipment checked. Mechanization of greenhouse operations has lagged far behind the pattern of agriculture in general. Disease is a particularly serious hazard in greenhouse farming, requiring constant attention and use of chemicals.

The factor of weather

WEATHER INFORMATION

The interaction of weather and living systems is a basic aspect of agriculture. Although great strides in technology have resulted in massive production increases and improved quality, weather remains an important limiting factor. Though man is not yet able to change the weather, except on a very small scale, he is capable of adjusting agricultural practices to fit the climate. Thus, weather information is of utmost importance when combined with other factors, such as knowledge of crop or livestock response to weather factors; the farmer's capability to act on alternative decisions based on available weather information; existence of two-way communication by which specific weather forecasts and allied information can be requested and distributed; and the climatic probability of occurrence of influential weather elements and the ability of the meteorologist to predict their occurrence.

Other weather-research benefits. Apart from the many applications of weather forecasting to current problems, meteorological research may benefit agriculture in at least three other ways: (1) improved planning of widescale land usage depends partly on detailed knowledge of plant-climate interactions; radiation, evapotranspiration, diurnal temperature range, water balance, and other parameters are measured and analyzed before a plan realizing maximum economic benefit for a given area is prepared; (2) agronomic experiments are combined with climatological documentation to obtain the greatest scientific and technological return; (3) problems of irrigation, row spacing, timing of fertilizer application, variety selection, and transplanting can best be solved with the aid of climatic environmental data; cultural practices related to artificial modification of microclimates should be based on research knowledge rather than personal judgment.

Observing climatic elements. The climatic elements the observation of which is valuable for agricultural purposes can be approached on an idealized threefold scale: (1) microscale observations of small areas for research designed to elucidate basic physical processes; (2) mesoscale climatic networks designed for practicing farmers to improve

Three classes of weather stations

their operations; and (3) macroscale regional networks intended for weather forecasting and for gathering basic climatic data (see also CLIMATE AND WEATHER). Macroscale stations can be further divided into first-order and second-order stations, the number and type of observations different for each. Micrometeorology demands the most elaborate array of measuring devices, while a second-order macroscale station requires the least; in fact, the latter station will measure only five elements: air temperature, rain, snow, humidity, and surface wind. A first-order macrostation will be equipped to measure 16 elements: global radiation, sunshine hours, clouds, net radiation, air temperature, soil temperature, rain, snow, hail, dew, fog, humidity, pan evaporation, pressure, upper air wind, and surface wind. Mesoscale measurements include 10 elements and microscale 27 (three of which are derived from others).

The World Meteorological Organization and the various national weather services are concerned with establishment and improvement of macroscale regional climatic stations, both first-class and second-class. Spaced at least 10 miles (16 kilometres) apart, their value for daily agricultural operations is limited, but they are useful for long-range planning and forecasting. Most parts of North America, Europe, and Australia have adequate networks of these stations, but wide gaps exist in the tropics, polar regions, and arid lands.

The degree day. One weather characteristic of agricultural value is the degree day. This concept holds that the growth of a plant is dependent on the total amount of heat to which it is subjected during its lifetime, accumulated as degree days. Common practice is to use 50° F (10° C) as a base. Thus, if the mean daily temperature for a particular day is 60° F (16° C), then 10 degree days are accumulated for that day on the Fahrenheit scale. The total number of growing degree days required for maturity varies with crop variety as well as plant species. Also, the minimum threshold temperature (the temperature below which the plant is damaged or unable to grow) varies with plants; *e.g.*, 40° F (4° C) for peas, 50° F (10° C) for corn (maize), and 55° F (13° C) for citrus fruits. Where studies have established the number of degree days required for maturity of a given crop, the planting dates can be scheduled for orderly harvest and processing. The system is helpful in selecting crop varieties appropriate to different geographical areas; it also has value in scheduling spray programs and predicting insect emergence.

Weaknesses of the degree-day concept

The growing-degree-day concept has certain weaknesses: (1) it assumes that the relationship between growth and temperature is linear (actually it is not); (2) it makes no allowance for changing threshold temperatures with advancing crop development; (3) too much weight is given to temperatures above 80° F (27° C), which may be detrimental; and (4) no account is taken of the diurnal temperature range, which is often more significant than the mean daily value.

WEATHER EFFECTS

The essence of the weather–agriculture interaction for the farmer lies in wise adaptation of operations to the local climate and in techniques for manipulating or modifying the local environment (microclimate) to minimize weather stresses on plants and animals. Many of these techniques have been practiced for centuries: seeding and cultivation, irrigation, frost protection, animal shelters, windbreaks, and others are methods of altering the microclimate. The climatic factors and their relation to plant growth in terms of protective techniques are important.

Solar radiation. Solar radiation is the ultimate source for all physical and biological processes of the earth. Agriculture itself is a strategy for exploitation of solar energy, made possible by water and nutrients. During daytime hours, solar radiation is delivered both directly and by diffused sky reflection. The incoming radiation that is not reflected by the surface or reradiated to outer space is the net radiation, which is the energy available for maintaining the earth's surface temperature. At night the net radiation is negative; that is, energy is lost to outer space by long-wave radiation, and none is gained. The net radiation balance varies widely throughout the world, setting limits on basic agricultural possibilities.

Leaf canopy's effect on solar-energy distribution

Photosynthesis. Photosynthesis is the process by which higher plants manufacture dry matter through the aid of chlorophyll pigment, which uses solar energy to produce carbohydrates out of water and carbon dioxide. The overall efficiency of this critical process is somewhat low, and its mechanics are extremely complex. It is related to light intensity, wavelength, temperature, carbon dioxide concentration in the air, and the respiration rate of the plant. The distribution of solar energy within the plant community is affected by the leaf canopy's density, height, and capacity to transmit the energy; these therefore affect photosynthesis. The leaf-foliage density is characterized by the leaf-area index, the total leaf area of a plant over a given area of land. The optimum leaf-area index will vary between summer and winter and between temperate and tropical regions, but it represents a key factor in the search for better crop management based on improved photosynthesis. The efficiency of radiation utilization by field crops has been measured, showing that an ordinary crop converts less than 1 percent of available solar energy into organic matter.

Photoperiodism. Photoperiodism is another attribute of plants that may be changed or manipulated in the microclimate. The length of a day is a photoperiod, and the responses of the plant development to a photoperiod are called photoperiodism. Response to the photoperiod is different for different plants; long-day plants flower only under day lengths longer than 14 hours; in short-day plants, flowering is induced by photoperiods of less than 10 hours; day-neutral plants form buds under any period of illumination. There are exceptions and variations in photoperiodic response; also, it is argued that the truly critical factor is actually the amount of exposure to darkness rather than to daylight. Temperature is intimately related to photoperiodism, tending to modify reactions to daylength. Photoperiodism is one determining factor in natural distribution of plants throughout the world.

The phenomenon has many practical applications. Selection of a plant or a variety for a given locality requires knowledge of its interaction with the photoclimate. Artificial illumination is used to control flowering seasons and to increase production of greenhouse crops. In plant breeding, such stimulation of flowering has greatly reduced the time span from germination to maturity, shortening the time necessary to develop new varieties. In sowing field crops, photoperiodism can be used to select the date of sowing to produce optimum harvest size. Crop yield is reduced both by planting in a season that will cause plants to flower early and by planting at a time that will cause very late flowering. In Sri Lanka (formerly Ceylon), certain rice varieties with a vegetative period of five to six months may extend their life to more than a year when planted in the wrong season, causing almost complete loss of yield. Cowpeas in Nigeria will flower early and produce many seeds only when planted in daylengths of 12 hours or less.

WEATHER CONDITIONS AND CONTROLS

Three cardinal temperatures

Temperature. Regardless of how favourable light and moisture conditions may be, plant growth ceases when the air and leaf temperature drops below a certain minimum or exceeds a certain maximum value. Between these limits, there is an optimum temperature at which growth proceeds with greatest rapidity. These three temperature points are the cardinal temperatures for a given plant; the cardinal temperatures are known for most plant species, at least approximately. Cool-season crops (oats, rye, wheat, and barley) have low cardinal temperatures: minimum 32° to 41° F (0° to 5° C), optimum 77° to 88° F (25° to 31° C), and maximum 88° to 99° F (31° to 37° C). For hot-season crops, such as melons and sorghum, the span of cardinal temperatures is much higher. The cardinal temperatures may vary with stage of development. For example, cold treatment near 32° F (0° C) of germinated seeds before sowing can transform winter rye into the spring type; such treatment, called vernalization, has practical application in cold-climate plants.

The range of diurnal temperature variation is also important; the best net photosynthesis is related to a large diurnal temperature range, or high daytime and low nighttime temperatures. Knowledge of the difference between leaf and air temperatures aids farmers in adopting protective measures. In middle and high latitudes, frost often occurs before the air temperature drops to freezing; in summer, heat injury to plants might be much more serious than that suggested by the air temperature alone. Because of this factor, farmers in Taiwan shade the pineapple fruit to prevent heat damage.

Soil temperature sometimes is of greater ecological significance to plant life than air temperature. Germination of seed, root function, rate of plant growth, and occurrence and severity of plant diseases all are affected by soil temperature. Since an unfavourable soil temperature during the growing season can retard or ruin a crop, techniques have been developed for modifying the temperature. The two most important methods are (1) regulation of the energy exchange and (2) altering the thermal properties of the ground. Incoming energy can be regulated by an insulation layer on or near the ground surface, such as paper, straw, plastic, or trees; the outgoing radiation can be reduced by insulation materials or by generating smoke or fog in the air. Thermal properties of the ground can be modified by cultivation or irrigation, increasing the soil's ability to absorb radiation, or by varying the rate of evaporation. Mulching is a common technique for soil temperature control. Carbon black or white material can change the soil's ability to absorb radiation. In the Soviet Union, for example, it was reported that 100 pounds of coal dust per acre (112 kilograms per hectare) caused a one-month advance in the maturity date of cotton.

Frost. Another aspect of temperature control is frost protection. Likelihood of damage from freezing temperature depends upon the plant species, the season, the manner of temperature change, the physiological state of the plant, and other factors. Orchards can be located so as to minimize the chances of frost damage.

Radiation and wind types of frost

Two types of frost are recognized: (1) radiation frost, which occurs on clear nights with little or no wind when the outgoing radiation is excessive and the air temperature is not necessarily at the freezing point, and (2) wind, or advection, frost, which occurs at any time, day or night, regardless of cloud cover, when wind moves air in from cold regions. Both types may occur simultaneously. Most frost-protection techniques can raise the temperature only a few degrees, while some are effective only against radiation frost.

Heating is probably the best known and most effective frost-protection measure. It is most effective on nights with a strong temperature inversion, a condition in which the air temperature increases markedly from the ground up to as high as 40 or 50 feet (12 or 15 metres). The depth of air to be heated is thus rather shallow, and the area over which a given temperature rise can be produced increases linearly with the strength of the inversion. Lacking a temperature inversion, heaters protect by radiating heat to the plants and the ground surface, and by emitting a layer of humid smoke that reduces the net outgoing loss from the ground.

In general, a large number of small heaters is most effective; large heaters set up convection currents that break up the warm ceiling and draw in cold air. For radiation-frost protection, the heaters are placed in "view" of the plants or trees, but for advective frost the heavier concentration is placed along the upwind border. Common fuels for the heaters include oil, coal, briquettes, and wood. Oil is most effective, because it can be ignited rapidly and extinguished easily. Heating is a costly technique; a few growers who tried it in England soon gave up the practice, and, even in places such as California, heating is becoming less common and is mostly restricted to a few high-value crops such as citrus fruits.

Wind machines for frost protection

The wind machine is popular for frost protection; although it affords less reliable results, its operating cost is much lower than that for heaters. These machines, which are like fans or propellers, break up the nocturnal temperature inversion by mechanically mixing the air, returning heat to the ground that was lifted during the day. The stronger the temperature inversion, the more effective is the wind machine, which is ineffective, however, against a daytime freeze or cold soil. Even under the best circumstances, ground-surface temperatures will rise very little; therefore, some operators install both heaters and wind machines, using the latter for strong-inversion nights and the former for wind-frost protection.

Flooding and sprinkling with water prevent excessive ground cooling by increasing the heat conductivity and heat capacity of the soil and releasing latent heat of fusion, or the heat given off when the water freezes. The temperature of the plant will not fall below the freezing point so long as the change of state from water to ice is taking place. Flooding has the disadvantage of retarding increase in soil warmth during the day; thus, it can be used effectively for only one or two nights. Sprinkling creates water particles in the air that reduce outgoing radiation, but plant temperature declines immediately on cessation of sprinkling, and the ice formation may cause damage to the crop. In general, successful protection by flooding and sprinkling demands much skill and judgment from the operator.

Brushing is a frost-protection technique in which shields of paper or aluminum foil are set up to reduce radiation loss to the sky; it has been used with fair success for tomato culture in California.

Massachusetts cranberry growers add a thin layer of sand to the soil periodically. The sandy surface warms up easily and cools slowly by radiation; it also reduces evaporation of its low water content. Sanding can raise the temperature of loam, clay, and organic soils, thus diminishing frost hazard. Windbreaks can also function as frost protection by reducing inflow of cold air and by shielding plants from the total night sky.

Spraying of harmless foams or gels on plants threatened by frost is a technique under investigation. The trapped air in the foam serves as insulative protection, while the foam can be designed to dissolve after any desired time interval. The technique has been explored for use on strawberries and other low-growing crops.

Irrigation. Irrigation is probably the most common form of agricultural microclimatic control practiced by man. The basic techniques of irrigation are discussed in the section *Irrigation and drainage* above; at this point it only remains to make mention of efforts to correct deficiencies in precipitation, the deficiencies that lead farmers to irrigate.

Cloud modification versus rainfall

Rainmaking. Attempts to increase the amount of precipitation from clouds by seeding them with salt or silver iodide have been made for nearly three decades. Both aircraft and ground generators have been employed, but the techniques are typically beyond the means of an individual farmer. Results suggest that cloud modification is entirely possible, but the proof of increased rainfall at a level of statistical significance is a difficult problem. Success has been greatest under atmospheric conditions where natural rainfall is most probable. The prospect of modifying winter clouds to increase snowfall in mountain areas appears to be somewhat more promising, however.

Most cloud-seeding efforts are expended in regions where precipitation is only marginal for agriculture. It is commonly assumed that at least 20 inches (500 millimetres) of rain per year, fairly well distributed, is required to maintain a stable farming community. Unfortunately, the years of large deficiencies in such areas are those with only limited opportunity for cloud seeding. Some observers believe that weather modification to increase precipitation may yet become practical and economically feasible; the legal, ethical, and ecological problems raised by the prospect will not be easily solved, however.

Humidity. The value of high humidity in the greenhouse is well known, but knowledge of humidity–plant interaction under field conditions is comparatively slight. Other things being equal, the evapotranspiration rate decreases with increasing humidity; thus, rate of water use is higher at low levels of humidity. The benefits of irrigation are apparently greater when the humidity is high, which simply means that the efficiency of water use increases with humidity.

Wind. Wind affects plant growth in at least three significant ways: transpiration, carbon dioxide intake, and mechanical breakage. Transpiration (the loss of water mainly through the stomata of leaves) increases with wind speed, but the effect varies greatly among plant species; also, the effect is related to temperature and humidity of the air. In arid climates, dry and hot winds often cause rapid, harmful wilting. In winter, with frozen soil, the damaging effect of increased transpiration resulting from wind can be serious because the lost water cannot be readily replaced. By contrast, increasing wind promotes carbon dioxide intake within limits; this benefits the rate of photosynthesis. The effects of mechanical wind damage vary from species to species; some show a definite decrease in dry matter production with increasing wind, while others (usually short plants) are unaffected. Because of the long-recognized need, shelterbelts, massive plantings of trees that change the energy and moisture balance of the crop, are positioned to protect crops and to increase yields. A shelterbelt perpendicular to the prevailing wind reduces velocity on both sides. A medium-thick shelterbelt can reduce wind velocity by more than 10 percent to a distance of 20 times the tree height on the leeward side and three times the tree height to the windward. The length of the shelterbelt should be at least equal to that of the field to be protected. The sheltered area will suffer much less soil erosion and mechanical damage than unprotected areas. Other microclimatic effects of shelterbelts include: (1) small daytime temperature increases and nighttime decreases; (2) the occurrence of radiation frost in the leeside may be promoted; (3) rate of evaporation in the sheltered area is decreased, depending on wind velocity; (4) snow accumulates near the shelterbelt, causing increased moisture storage in dry farming.

Shelterbelts for crop protection

The overall effect of a shelterbelt is complicated but probably beneficial. There is much evidence that they increase efficiency of water use not only in subhumid and semi-arid regions but also in true deserts where oasis-type irrigation is practiced. The response to shelterbelts, however, depends on the species. Crops of low response to wind protection are the drought-hardy small grains and maize grown under dry farming conditions. Rice and forage crops such as alfalfa, lupine, and clover are moderately responsive. Crops that benefit most from wind protection are garden crops, such as lentils, potatoes, tomatoes, cucumbers, beets, strawberries, watermelons, deciduous and citrus fruits, and other tender crops, such as tobacco and tea. Some authorities assert that in strong wind areas shelterbelts will produce an average 20 percent yield increase, which is net gain of 15 percent when allowance is made for the land occupied by the belts themselves. Trees can be grown almost anywhere, even in the desert; tall plants such as corn (maize), sorghums, or even elephant grass can also be employed in arid regions by including them in the irrigation schedule. It would appear that windbreaks are among the most practical means of beneficial weather modification in agriculture.

The effects of pollution

Practically all forms of technology exact a certain price in environmental damage; agriculture is no exception. Agriculture in turn is sometimes damaged by undesirable by-products of other technologies (see also CONSERVATION OF NATURAL RESOURCES: *Pollution control*).

Air has physical properties and a chemical composition that are vital parameters of life for both plants and animals. Temperature, water vapour, movement, oxygen, and carbon dioxide in the atmosphere have a direct effect on food and fibre production. Air quality is changed by introduction of contaminants into it, and agricultural activities using such air may be affected adversely. Damage to plants by air pollutants is related to meteorological conditions, particularly temperature inversions in the atmosphere.

AIR POLLUTION

Air pollution damage to agriculture. For more than a century air pollution has affected agriculture. Burning coal and petroleum produce sulfur oxides. Fluorides result from smelting and glass and ceramic manufacture. Rising levels of ammonia, chlorine, ethylene, mercaptans, carbon monoxide, and nitrogen oxides are found in the air. Motor vehicles and growing population produce photochemical air pollution affecting not only the urban concentrations but also the contiguous rural areas. The mixture of pollutants from all sources, including agriculture, has released a host of contaminants into the air, such as aldehydes, hydrocarbons, organic acids, ozone, peroxyacetyl nitrates, pesticides, and radionuclides. The effect of these pollutants on food, fibre, forage, and forest crops is variable, depending on concentration, geography, and weather conditions. Damage to crops by air pollution, of course, brings economic loss as well.

Types of air contaminants

The effects of air pollution on plants and animals may be measured by the following factors: (1) interference with enzyme systems; (2) change in cellular chemical constituents and physical structure; (3) retardation of growth and reduced production because of metabolic changes; (4) acute, immediate tissue degeneration. Pollutants that enter the air from sources other than agriculture and that produce plant response are classified as: (1) acid gases; (2) products of combustion; (3) products of reactions in the air; and (4) miscellaneous effluents.

Acid gases. Acid gases include fluorides, sulfur dioxide, and chlorine. Hydrogen fluoride is extremely toxic to plants; some plants are injured by contact with concentrations of less than one part per billion. The damage apparently occurs initially to the chlorophyll, producing a mottled chlorosis and later killing the cells. Plants vary in degree of tolerance to hydrogen fluoride; usually the plants that accumulate fluoride readily are the most tolerant. Corn is more susceptible than tomato. All plants are most susceptible to fluoride injury during periods of rapid growth.

Sulfur dioxide given off in combustion of oil and coal commonly causes necrosis (cell death) of the leaf (Figure 10). At certain concentrations, sulfur dioxide will affect plants if the stomata (minute pores in the epidermis of a leaf or stem) are open. High light intensity, favourable growth temperatures, high relative humidity, and adequate water supply are conducive to open stomata. Plants that close their stomata at night can tolerate sulfur dioxide much better during that period. Conifers are more susceptible in spring and early summer, when the new needles are elongating. The sulfur dioxide absorbed by the leaf cells unites with water to form a toxic sulfite, but this is slowly oxidized to a relatively harmless sulfate. The toxicity of sulfur dioxide thus is a function of the rate at which it is absorbed by the individual plant; rapid absorption will cause greater injury. Chlorine damage to plants is somewhat rare; its typical symptoms are bleaching and necrosis of the leaf.

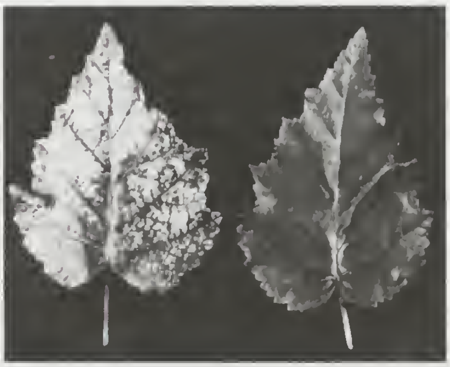

Figure 10: *Air pollution injury to vegetation.*
(Left) The effect of sulfur dioxide on a white birch leaf.
(Right) A normal leaf.

Products of combustion. The primary products of combustion are ethylene, acetylene, propylene, and carbon monoxide. Of these, ethylene is known to affect plants adversely; while the others may also do so, it would require higher concentrations of them than typically occur

Effects of ethylene

in polluted air. For many years it was observed that illuminating gas (3 percent ethylene) leaking from pipelines caused damage to nearby vegetation. Now, with the use of natural gas, ethylene in the air is derived mostly from certain chemical industries and from automobile exhaust. Greenhouse flowers in metropolitan areas are typically damaged by ethylene. Such injury appears to be caused by excessive speeding up of the life process, thus bringing on damage. Ethylene was first identified as affecting plant life over large areas in the field by its effects on cotton and other plants near a polyethylene factory.

Ethylene, ozone, and peroxyacetyl nitrate are produced as reaction products in the air and are clearly implicated in plant injury. In addition, certain bisulfites and nitrogen dioxide are under suspicion; there are probably others. Ozone is a major air pollutant affecting agriculture. Damage has been identified in a number of field crops, including spinach, tobacco, fruits, vegetables, forest trees, and ornamentals. Symptoms of ozone toxicity appear as flecks, stipple, streaks, spots, tipburn, and premature yellowing of the foliage; these may be visible only on the upper leaf surface. Peroxyacetyl nitrate and its analogs produce symptoms called silver leaf and leaf banding, which have been observed in the Los Angeles area and elsewhere for many years.

The adverse effects of airborne radioactive contaminants on the agricultural economy at the present time are small.

Air pollution by agriculture. Contributions of agricultural technology to air pollution include pesticides, odours, smoke, dust, allergenic pollens, and trash. The widespread public concern about pesticides makes it imperative that pesticide technology be carefully controlled and that search for better methods be pursued vigorously.

Persistence in pesticides

Pesticides. The problem of persistence in pesticides can be highlighted by noting that this attribute exists in a range from moderately persistent (a lifetime of one to 18 months—2,4-D, atrazine); persistent (lifetime up to 20 years—DDT, aldrin, dieldrin, endrin, heptachlor, toxaphene); or permanent (lead, mercury, and arsenic). Presumably, the less persistent types should be more desirable, other things being equal; but those that degrade rapidly, such as the organophosphate insecticides, are extremely toxic and nonselective, which encourages rapid emergence of resistant insects and destroys their natural enemies. Thus, it is apparently not possible to adopt chemicals that function without some drawback or disadvantage.

Whether pesticides are applied by spraying or by surface application, air is the usual medium through which the chemicals move to their intended and unintended targets. Reliable data on how pesticides behave in air, such as distance travelled, are lacking, because adequate monitoring is unavailable. Their chemical and physical nature, method of application, and the atmospheric conditions will influence their concentration and ultimate fate. There is no doubt that pesticides may be transported long distances on dust particles. The rate of removal from air is difficult to predict, but in the long run the chemicals return to earth.

Odours, pollen, and dust. Odours from animal concentrations are recognized as being highly undesirable to air quality. Where these operations exist contiguous to urbanized areas, public reaction is usually unfavourable. Disposal of animal waste on the land may worsen the odour problem; in addition, high wind may move dry increments into the air. Smoke is emitted by operations designed to dispose of crop residues, or by controlled burning of weeds and brush. Air quality is also affected by transmission of allergenic pollen such as ragweed pollen, which can be blown for hundreds of miles.

Improper land use and treatment can cause considerable deterioration in air quality. Practices that strip the soil of plant growth or crop residues for long periods contribute to wind erosion, particularly in dry-farming areas. Fortunately, the technology of preventing wind erosion is well understood and widely used. Trash related to agriculture is moved freely by wind and distributed in unwanted fashion. Hulls of rice and wheat and cotton-gin trash are examples of this kind of airborne nuisance.

In contrast to most other technologies, however, the agricultural variety offers a major beneficial contribution to air quality. The photosynthesis of green plants removes carbon dioxide from the air and adds oxygen to it, thus helping to maintain the life-giving balance between these gases.

SOIL AND WATER POLLUTION

Pollutants damaging to agriculture. Soil and water pollutants that may adversely affect agricultural operations include sediment, plant nutrients, inorganic salts and minerals, organic wastes, infectious agents, industrial and agricultural chemicals, and heat.

Sediments in dual pollution role

Sediment. Sediment is a resource out of place whose dual effect is to deplete the land from which it came and impair the quality of the water it enters. Aside from filling stream channels, irrigation canals, farm ponds, and irrigation reservoirs, sedimentation increases cost of water clarification. Suspended sediment impairs the dissolved-oxygen balance in water. The recreational value of farm ponds is diminished by sediment, while soil depleted farmland is reduced in value.

Plant nutrients. Nutrients of plants become resources out of place when they appear in groundwater and surface water; in fact, they become serious pollutants. Unwanted aquatic plants are nourished by plant nutrients derived from agricultural runoff, feedlots and barnyards, municipal and rural sewage, and industrial wastes. Aquatic plants clog irrigation and drainage structures, thus increasing maintenance cost and reducing capacity. Nitrates and nitrites in groundwater, which can poison human beings and livestock, result from both agricultural and industrial operations.

Inorganic salts and minerals. Inorganic salts and minerals that impair the quality of soil and water are derived from natural deposits, acid mine drainage, industrial processes, and drainage flow from irrigated areas. Salt accumulation on irrigated soils causes the most damage and loss in this category. A high proportion of sodium in irrigation water supply affects plant life adversely (see below *Salinity*). More than just a trace of boron is highly toxic; therefore, water used in municipal and industrial processes involving borax may not be usable for agriculture.

Organic wastes. Organic wastes emanating from municipal sewage, garbage, food-processing industries, pulp mills, and animal enterprises are attacked by aerobic bacteria. When this occurs in water, the oxygen content of the water is depleted or reduced to zero, at which point the anaerobic bacteria complete the process of reducing the wastes to inert material. This produces septic conditions that make the water unfit for recreational use, farmstead supply, or crop irrigation.

Diseases transmitted by water and soil

Infectious agents. Where not carried by wind, infectious agents are transmitted mainly by water and soil. Bacterial and virus diseases of crops are spread by machines that move contaminated soil. Insects are prime carriers of these diseases. Weed seeds are spread by irrigation water, as are nematodes. Animal diseases transmitted by water and soil include leptospirosis, salmonellosis, hog cholera, mastitis, foot and mouth disease, tuberculosis, brucellosis, histoplasmosis, Newcastle disease, anthrax, coccidiosis, and many others. Mosquitoes breeding in stagnant water can transmit encephalitis. Most crops and livestock in the world are susceptible to one or more highly infectious disease that may be transported by soil or water. The cost of losses from these diseases is staggering.

Chemicals. Organic chemicals in soil and water, such as detergents, insecticides, herbicides, fungicides, nematocides, rodenticides, growth regulators, and defoliants, can have adverse effects on agriculture. The application of persistent insecticides to potato lands has led to residues in sugar beets grown in the same soil the following year, for which there are no tolerances. Fish have been killed in farm ponds because of drainage of insecticide pollutants. Use of heptachlor (no longer recommended) to control alfalfa weevil led to soil contamination and uptake by hay; dairy cows that ate the hay produced milk containing heptachlor.

Aerial and ground application of herbicides on nonagricultural lands (utility rights-of-way, roadsides, industrial sites) often cause damage to nontarget crops. Herbicide wastes may enter drainage or irrigation ditches and create trouble. The presence of chemical residues in agricultural commodities can cause serious problems ranging from confiscation to loss of public confidence. Practically all aspects of chemical usage are now regulated or restricted by government.

Heat. Introduced into water by industrial processes, heat can have a detrimental effect on fish and other creatures in the water; damage to recreational value can result. But, though heat is a water pollutant, its effect is minor with respect to agriculture.

Pollutants from agriculture. Some pollutants from agriculture have adverse effects on agriculture itself, as excesses of plant nutrients and salts from irrigation. These pollutants and others also affect the environment at large.

Eutrophication. Eutrophication occurs in a body of water when an increase of mineral and organic nutrients has reduced the dissolved oxygen, producing an environment that favours plant over animal life. The resulting algae and other water plants tend to choke other forms of life in the oxygen competition, especially where carbon and phosphorus are plentiful. Doubtless, much phosphorus in streams and lakes is delivered from agriculture, but primarily through soil erosion rather than runoff. Though the principal source of phosphorus is apparently municipal sewage-treatment plants, direct runoff from feedlots may also contain large amounts. The solution to the problem of phosphorus in surface water lies in using good soil-conservation practices and in minimizing runoff from animal concentrations and manure.

In contrast, identification of nitrate sources in water supplies has suffered from conflicting evidence. Where nitrate is found in water, some have concluded it came from chemical fertilizers, while others have suggested it came from natural soil nitrification or nitrification of sewage effluent or animal wastes. The problem has serious aspects, because nitrate can cause serious illness in human beings. One difficulty in identifying nitrogen sources lies in the fact that it is present in soils for reasons other than fertilization; the growth of legumes, for example.

Salinity. Salinity is a major problem in irrigation agriculture. Through evapotranspiration, salts in the irrigation water become more concentrated in the drainage effluent. It is therefore claimed that water quality is seriously impaired by irrigation agriculture. Irrigation water always contains some salt, most of which is excluded by the plant roots; since the evaporated water is pure, the soil accumulates the residual salt, which is added to what the arid soils already have in abundance. This accumulation of salt must be removed if plants are to be grown at all, and it is removed by leaching with excess water.

Survival of an irrigated arca will depend, therefore, on a favourable salt balance: salt leaving the area must equal or exceed that received in the water supply. The irrigation farmer is not actually "producing" a contaminant but is transferring one in a more concentrated form. Future intensified use of limited irrigation water may add to the severity of this problem. Where the return flow is readily recoverable, as from tile drains or pumped wells, it could be purified by a desalination process, returning the purified fraction to the watercourses and disposing of the concentrated-salt fraction in such a way that usable groundwater is not affected.

Agricultural processing wastes. The wastes from processing of agricultural products represent another pollution hazard. These include runoff or effluent from sawmilling, pulp manufacture, fruit and vegetable canning, cleaning of dairies, slaughtering of meat animals, tanning, manufacturing of cornstarch and soy protein, sugar refining, distilling, wool processing, and many others. The runoff from agricultural enterprises can contain disease organisms and other infectious agents. Insects associated with agriculture can transmit diseases. Plant diseases move from agriculture to lawns, gardens, parks, and golf courses.

Monitoring pesticides. The monitoring of pesticides in water has been carried on in various areas since World War II. Some of the monitor networks, backed by analysis laboratories, are quite extensive. The accumulated data show how and when certain pesticides move from target areas into other parts of the environment. Ponds and catch basins sometimes show measurable amounts of pesticide rcsidues from water leaving fields. Although most organic insecticides are hydrophobic and almost insoluble in water, they can become attached to materials suspended in water; but, after these materials settle, the rcmaining amounts of insecticide residues usually becomc ncgligible. This confirms the earlier supposition that the movement of chemicals from target areas is greatest when silt and organic loads are high in runoff watcr.

Transport pattern of pesticides

Levels of pesticides in soils arc constantly changing. So many variables and processes are involved, that rates of accumulation of even the most persistent insecticides are quite variable and difficult to detcrmine. Soil monitoring programs are underway, howcvcr, and are providing much-needed information. The problem of accumulation in soils arises because the tiny organisms in soil are not capablc of degrading many pesticides at rates sufficiently high to prevcnt soil and also water pollution. Thus, the persistent types, such as DDT and other chlorinated hydrocarbons, remain available for absorption by higher animals (including human beings) and for causing harm to nontarget organisms. (R.E.S.)

PRINCIPLES AND PRACTICES OF ANIMAL HUSBANDRY

Animal breeding

Animal breeding is the controlled propagation of domestic animals. Its aim is the improvement of qualities considered desirable by man. Breeding procedures involve the application of several basic sciences, chiefly reproductive physiology, genetics, and statistics. This article deals with the practical application of scientific principles to the selection of superior animals and the planning of mating combinations. The fundamental biological principles underlying animal breeding are discussed in the articles GENETICS AND HEREDITY and REPRODUCTION AND REPRODUCTIVE SYSTEMS.

Uses of highly bred animals

Animals are bred for utility, sport, pleasure, and research. Dogs, for example, have been bred to serve as watchdogs, police dogs, hunters, sheep dogs, and pets. Many species of small mammals, especially rats, mice, rabbits, and guinea pigs, are bred for research, chiefly in genetics, physiology, and medicine. The basic principles of breeding are the same no matter what the animal species or the purpose in breeding may be, but the practical approach to the problem may differ in several respects, depending on such considerations as the mode and rate of reproduction and the relative effects of genetic and cnvironmental factors on the traits of greatest interest.

The term population is used in this article to denote a group of interbreeding individuals; *i.e.*, a breed, or strain within a breed, which in some respects is genetically different from other breeds, or strains, of the same species. The word purebred is used here in its scnse of referring to animals registered in the herdbook maintained for a certain breed, or to animals eligible for such registration, and the mating of purebred animals is called pure breeding. It is to be understood that genetically pure breeds (homozygous for all traits) do not exist.

The objectives of animal breeding vary with regard to species, local conditions, and time. Early in history horses were bred mainly for riding or loading purposes; later they were bred for traction; and nowadays, to a large extent, for sport (racing and hunting). In North America and western Europe, cattle populations are specialized for beef or milk production, or bred for a combination of both. In southern Europe and in many parts of Africa and Asia, oxen are still produced for pulling plows or carts. Some breeds of sheep are specialized for wool production, some for meat, and one breed, the Karakul sheep, is bred for fur production (Persian lamb). Pigs always are bred for meat production, but they may be specialized to produce a certain type of meat, either pork or bacon. At one time, chickens were bred for the combined production of eggs and meat, but in the Western world there is now a pronounced specialization of breeds and crosses to produce either eggs or meat.

EVALUATION OF ANIMALS

In breeding farm animals for utility, selection must be based as far as possible on objective measurements of traits that are decisive for the economy of production. Judging animals on the basis of appearance alone has not become obsolete but its importance has been reduced. Certain traits, of course, are difficult or impossible to measure objectively. In all kinds of horses, for example, the legs should be well proportioned in relation to the body and free from faults and weaknesses; this judgment is difficult to render quantitatively. Similarly, the strength of the legs is important in cattle and pigs, but difficult to measure. In dairy cows, the attachment of the udder to the body is difficult to measure; but it is significant, and it can be judged and scored. In mink breeding, a judging of the animals with regard to fur quality and shade of colour is necessary and cannot, so far, be substituted by laboratory tests. In the breeding of pet animals, such as dogs and cats, judging the animals for conformity with breed standards is usually decisive in determining their market value.

Judging animals on appearance

Actual measurement of an individual animal's performance is a fairly recent innovation in animal breeding, except with regard to Thoroughbred horses, the selection of which for centuries has been based on speed at standard racing distances. Systematic recording of milk production in dairy cows started in Denmark in 1895, and the movement spread rapidly in northwestern Europe and North America. In several countries, young beef and dairy bulls are tested at special stations for rate of growth and muscle development. In sheep breeding, the number of lambs borne by each ewe is recorded, as is the weight of the lambs at five months of age. The recording of growth rate, feed consumption, and carcass quality of pigs began in 1907. Progeny testing and performance testing (see below *Methods for estimating breeding values*) has subsequently been added to judge young males (bulls, rams, and boars) intended for breeding. The productivity of sows is measured by recording the number of pigs in each litter at birth and their weight at three weeks of age. An ultrasonic technique measures the thickness of backfat on live pigs. Special nests with hinged doors (trapnests) were employed to record the egg production of individual hens from the end of the 19th century until the introduction of individual laying cages made trapnests unnecessary. The recording of individual performance in breeding populations of farm animals developed with great rapidity after World War II, in terms of both frequency of use and refinement of methods. It may be considered to be the very foundation of progress in breeding programs.

Judging animals on performance

Genetic and environmental variation in animal traits. The traits of animals in any population may be classified roughly into two groups; viz., qualitative and quantitative traits. Qualitative traits show discontinuous variation; for example, coat colour, presence or absence of horns, certain blood characteristics (*e.g.*, blood types), presence or absence of particular enzymes, and existence of metabolic defects and congenital malformations (*e.g.*, bleeding disease [hemophilia] in dogs). In general, the inheritance of qualitative traits is relatively simple, in accordance with the laws of heredity, and environment plays only a minor role in their variation.

The quantitative traits show continuous variation between the extreme variants, the mean type being, as a rule, most frequent. Growth rate, live weight, body measurements at mature age, milk yield and composition in cows; body length and backfat thickness in pigs; wool yield and quality in sheep; and egg production in fowl are typical examples of quantitative traits. As a rule, such traits are influenced by many genes (polygenes), each gene exerting relatively small effect, and environmental factors are responsible for a considerable part of the variation.

There is, in fact, no distinct borderline between qualitative and quantitative traits. A congenital malformation, for example, may be determined by a major gene, as well as a number of polygenes, and the latter may cause a considerable variation in the expression of the trait. Similarly, variation in the expression of a trait regulated by a single gene may be caused by environmental factors. Nevertheless, this classification is useful because typical qualitative traits can be analyzed with regard to a single gene and its behaviour; whereas quantitative traits are best studied by statistical methods that permit one to proceed without knowledge of the number of genes involved or their interrelations. By using appropriate statistical methods, for example, it is possible to estimate the fraction of the total variation in the population that is caused by the additive effect of the genes; this fraction is termed the heritability. A heritability of 1.00 indicates that all the variation observed in the population of the trait in question is genetically determined; a heritability of 0.00 indicates that the variation is wholly environmental in cause; and when the heritability is 0.50 the genetic and environmental factors are equally responsible for the observed variation of the trait.

A few estimates of heritability of traits are given to illustrate typical values. In horses: pulling power, 0.25. In dairy cows: height at withers at three years of age, 0.45; milk yield at first lactation, 0.30; fat and protein content of milk, 0.55; resistance to mastitis, 0.30. In beef cattle; daily weight gain (from weaning to slaughter), 0.40. In sheep (Merinos): yield of clean wool, 0.45. In pigs: daily weight gain (from weaning to slaughter) in group feeding, 0.30, in individual feeding, 0.60; backfat thickness, 0.50; resistance to atrophic rhinitis, 0.25. In chickens: egg production (in first laying year), 0.30; egg size, 0.50; resistance to leukosis, 0.10. In general, heritability is relatively low for such traits as fertility and resistance to infectious diseases, and it is high for growth rate, body size at mature age, and composition of cows' milk.

Heritability of traits

The magnitude of environmental effects, and to some extent also the additive genetic effects, may vary considerably between different populations of the same species; therefore, heritability estimates also vary and cannot be considered as constants for the various traits. For example, as noted above, when the heritability of growth rate of pigs is estimated from individual-feeding data, it is twice as high as when it is estimated from group-feeding data. In spite of these limitations, heritability estimates for quantitative traits have proved to be of great value in planning animal improvement programs.

Methods for estimating breeding values. The breeding value of an animal depends on the genes it passes on to its offspring. Each individual offspring receives a random sample of one-half of the genes from each of the parents.

Concerning qualitative traits with known inheritance patterns, the situation is relatively simple. A dominant gene manifests its presence in the physical character (phenotype) of the individual even when the gene it is paired with is different—that is, in the heterozygous condition. A recessive gene also can be recognized but only when it is present in duplicate (the homozygous state). In both cases, of course, there must be no complications caused by modifying polygenes or environmental factors. The breeder can then select for or against the trait according to his wishes. To recognize heterozygous carriers of recessive genes by visual inspection of the animals is impossible in most cases, but it can be done by mating the suspected carrier to a certain number of known heterozygotes or to its own offspring.

The breeding value of a quantitative trait may be assessed on the basis of the merits of: (1) the individual himself, (2) his ancestors, (3) his collateral relatives, (4) his progeny, or (5) a combination of any two or more of the above. The relative value of these different approaches depends on the heritability of the trait and the rate of reproduction. With regard to quantitative traits that are sensitive to environmental influence, it is often advisable to use the deviation of the individual's record from the mean record of the herd, rather than the individual's record itself. This procedure eliminates, or at least reduces, the effect of

Breeding values

nongenetic differences between herds. Each of the above methods of assessing quantitative traits has its own uses (as discussed below).

Individual merit. If it is assumed, for example, that a cow in her first lactation has produced 10,000 pounds (4,500 kilograms) of milk, and that her contemporary herd mates in the corresponding lactation have produced 8,900 pounds (4,000 kilograms) on average, then the phenotypic merit of this cow is 1,100 pounds (500 kilograms) above that of her contemporaries. By this procedure, environmental effect is minimized. When cows of different age (or undergoing different lactation periods) are compared, it is necessary to correct the yield of each individual to a standard age, because the yield increases until the fourth or fifth lactation. The fat content of the milk is much less influenced by environment and by individual age; therefore, no age corrections are needed, and individuals can be compared directly on their actual records. The same principles apply to other traits and other species of animals.

Ancestor merit. The merit of ancestors is usually the first available information on the breeding value of an individual, and such pedigree information, therefore, is valuable as a rule. With each earlier generation in the pedigree, however, the value of this information is halved. Furthermore, since a grandparent can pass his genes to a grandson or a granddaughter only through one of its parents, the more information known about this parent, the less valuable is the information known about the grandparent. For example, if a reliable progeny test (see below) shows that the sire of an animal has a high breeding value, there is no need to consider the parents of that sire. In many cases, especially in horse and dog breeding, the importance of long pedigrees has been greatly exaggerated.

Judging by sibs

Merit of collateral relatives. The genetic similarity between an individual and a randomly chosen full sib (brother or sister) is the same, on average, as that between the individual and one of his parents; and an individual's genetic similiarity with a half-sib is the same as that with one of his grandparents. An individual, however, can have many more full sibs and half-sibs than parents or grandparents, and the sibs, therefore, may be of much greater value than parents or grandparents for estimating the breeding value of the individual. In pigs, rabbits, dogs, and fowl, the number of full sibs can be fairly large, and in artificial insemination of cattle the number of half-sibs can be very large.

Progeny merit. Progeny tests yield the final information on an animal's breeding value. The relative importance of such tests increases with decreasing heritability of the trait, and it is especially valuable for sex-limited traits, as, for example, in testing a bull's breeding value with respect to the milk yield of his daughters. The lower the heritability of a given trait, the larger a progeny group is needed for a reliable test of the individual.

Combined methods. Information from two or more of these methods can be combined into a single estimate of the individual's breeding value. In such circumstances, the different criteria should be weighted according to their expected contribution to the accuracy of the final estimate.

THE BREEDING PROGRAM

The genetic improvement of a herd or a breed requires careful planning with regard to the choice of animals for breeding and the mating combinations that are carried out.

Methods of selection. Selection of breeding animals can be carried out in different ways. Among the more important are mass selection, pedigree selection, family selection, and progeny selection.

1. Mass selection is based solely on individual merit. Applied to traits with high heritability and about equal manifestation in both sexes, mass selection can be expected to give good results. With decreasing heritability the efficiency decreases, and for sex-limited traits (and heritability considerably below 0.5) it is always inefficient.

2. Pedigree selection depends on the merits of the ancestors. It is valuable in the first selection among young animals, especially when the heritability of the traits is high. Relying solely on pedigree selection, however, results in very slow progress.

Family selection methods

3. Family selection is based on the merits of collateral relatives, such as full sibs or half-sibs, and it is used mainly as an aid to individual selection. It is especially valuable with regard to sex-limited traits, for traits with low heritability, or when some animals have to be slaughtered, as for determining the carcass quality. In the selection of young males for breeding, for example, no data may be available on their individual performance; *e.g.*, egg production in the fowl. When sib groups of pullets start laying early in the autumn, the cockerels may be selected for breeding on the laying records of their full sibs and half-sibs. Similarly, young bulls may be selected mainly on the milk records of their paternal half-sibs; that is, on the progeny tests of their sires. Individual pigs may be selected on the basis of carcass tests made on their sib groups. With regard to traits that can be recorded for all the animals alike, males and females, selection of individuals can be based simply on their family average or on an index that combines the individual's own performance and the average for the rest of the family. A simple procedure, applicable in dog and pig breeding, would be to select the best individual from the best litter.

One difficulty in the application of family selection is that systematic environmental differences may occur, especially between full-sib groups, and these tend to mask the genetic differences. When inherited defects appear in sib groups, there is a certain risk that some of the healthy animals carry a hidden gene for the defect.

4. Progeny selection has been applied with great success in dairy cattle breeding, and in general it is valuable in all types of livestock when applied to sex-limited traits and traits with low heritability. Early progeny testing of males on a sufficient number of offspring and an effective selection among those tested are very important. The disadvantage of selection of sires on progeny testing is that it means increased length of the generation interval and thereby tends to slow down the rate of genetic improvement.

In general, it is not necessary to include all the traits used for selection in an overall index; for example, all animals used for breeding should possess normal fertility, and those that do not should be excluded from the breeding program. Also, as a rule, any animal known to be a carrier of a gene for a serious metabolic or morphological defect should be eliminated even if the merits for some other traits are fairly high.

Stepwise selection

Usually selection is made in a stepwise fashion. With regard to dairy bulls, for example, selection on the basis of pedigree can be made soon after birth; a second selection can be made later based on growth rate during the first year of life and fertility in the first series of inseminations; and finally a third selection can depend on the results of progeny testing, when offspring are old enough to be judged.

Mating systems. *Random mating.* Random mating implies that each possible mating in a population has the same probability of occurrence. Only artificial selection by the breeder can really be eliminated; however, a certain amount of natural selection always takes place. Random mating often is used in breeding experiments to minimize genetic changes in a control population with which selected populations are compared.

Inbreeding. Inbreeding may be defined as mating of individuals more closely related than the average of the population. It increases the homozygosity and decreases the heterozygosity of the inbred animals. The so-called inbreeding coefficient is a measure of the loss of heterozygosity due to inbreeding, and it is expressed as a fraction, or percentage, of the amount of heterozygosity present when inbreeding started. After one generation of mating between full sibs or mating of sire with daughter or dam with son, the heterozygosity of the offspring is reduced by 25 percent (or the inbreeding coefficient is 25 percent). In the mating of half-sibs or double first cousins the inbreeding coefficient is 12.5 percent. Mating of single first cousins gives an inbreeding coefficient of 6.25 percent, and that of half first cousins 3.12 percent. Mating between full sibs in two successive generations decreases the heterozygosity by 37.5 percent, and in three generations by

50 percent. So-called inbred lines are produced by continuous consanguineous matings in several generations; genetic variation decreases within each line and increases between separate lines. In experiments with mice, rats, and guinea pigs, full-sib matings have been continued through many generations. Farm animals and birds are much more sensitive to inbreeding, and usually full-sib matings can be continued for a few generations only because of a marked decrease in viability and fertility.

Inbreeding in small populations

Breeding within small populations, such as a herd or flock, without infusion of new animals from outside, leads automatically to a certain amount of inbreeding. In farm mammals, each male is invariably used to serve a large number of females, and under such conditions the increase of the inbreeding coefficient per generation in a closed breeding unit can be estimated simply by dividing 100 by eight times the number of males used. Thus, when only one homebred sire is used, the decrease in heterozygosity in each generation is 12.5 percent. When artificial insemination is used, a small number of sires again are used to serve a large number of females. Nevertheless, the reduction in heterozygosity may be relatively small in such cases, because many young sires are used for progeny testing, and several tested sires enter into service each year. The modern trend in artificial insemination is to use the tested sires for only relatively short periods of time, after which they are replaced with younger sires, which presumably have made even better records. Such rapid turnover in sires serves also to reduce the length of the generation interval in breeding programs.

Inbreeding increases the homozygosity of unfavourable as well as favourable genes. As a result there is a segregation of various kinds of congenital defects and, more important, a general decline in fertility and viability of the inbred animals. The latter finding has been demonstrated in numerous experiments with farm animals, especially pigs and poultry. In experiments with laboratory animals it has been shown also that the sensitivity to unfavourable environmental influences increases with inbreeding. Although the decrease in fitness resulting from inbreeding is a general phenomenon, the amount of decrease is dependent on the genetic constitution of the animals used for inbreeding.

Linebreeding is a form of mild inbreeding designed to concentrate the genes of a certain ancestor in a strain of animals. The most intensive form of linebreeding is repeated backcrossing to a particular parent, but usually a more distant relationship is preferred; for example, a female may be mated to her grandsire or uncle.

Outbreeding. Outbreeding is defined as mating individuals less closely related than the average of the population. The degree of outbreeding can vary, just as that of inbreeding can. In some cases, it is even possible to make crosses between species, as in the crossing of the horse and ass for the production of mules. The term crossbreeding, however, usually refers to crosses between breeds within the same species. Crosses often are made between more or less inbred strains or lines of the same breed (called, respectively, strain and line crosses).

Crossbreeding

Crossbreeding has been practiced for a long time, and it also has been subjected to experimental research in the United States and Europe. Various methods have been developed and tested, with generally favourable results. The main function of crossbreeding is to increase the heterozygosity of the offspring. One of the breeds selected may be superior in certain traits and the other breed may excel in other traits. It can be expected, then, that the first-generation crossbred animals will be about intermediate to the parental breeds with respect to both traits. In some cases, however, the first-generation animals are somewhat superior to the better parental breed with regard to total merit. When the average quality of the first generation exceeds the average of the two parental breeds, the phenomenon is called heterosis, or hybrid vigour. Heterosis is displayed mainly in the so-called fitness traits, fertility and viability. It is thought to result from interaction of different forms (alleles) of a given gene (a phenomenon called overdominance) or from interactions of quite separate genes (epistasis). Crossbreeding thus is a way of utilizing nonadditive gene effects that cannot be exploited by selection within the separate breeds. When the heterozygosity is increased, the number of different genes is increased, a result that probably makes the animals better able to adapt to environmental stress.

Rotational crossbreeding

Backcrosses (crosses of crossbred offspring to one of the parental breeds) and successive three-breed crosses seem to have an advantage when maternal influence on the offspring is important; crossbred sows, for example, generally take better care of their young than purebred sows do. Rotational crossbreeding, usually involving three breeds, is a favoured method in commercial pig breeding since it necessitates purchase of males only. The first cross is made between breeds A and B, for instance, and the female offspring are mated to a boar of breed C; the females resulting from this cross are then mated to a boar of breed A, and in the next generation a boar of breed B is used, and so on.

Many experiments have been carried out on the crossing of inbred lines of the same breed or of different breeds. Generally, fertility and viability are restored even in the first crossbred generation. It has been possible with this technique, for example, to produce commercial "hybrid chicks" with superior egg-laying performance. Because the individual inbred lines are poor producers, the hybrid chicks are usually developed by a four-way cross. This is carried out by mating the offspring from crossing of lines A and B with the offspring from crosses between lines C and D, producing in effect a "double" hybrid. In order to obtain the best possible result, a large number of lines are tested in various crosses for combining ability—that is, ability to produce desirable results from crossing. Most of the eggs marketed in North America and western Europe are produced by hybrid chicks.

Similar methods of breeding have been tried also on pigs and cattle, but the results have been less favourable. With these animals the market value of the individual is so high that it is impossible for breeders to keep the costs of developing and testing inbred lines within reasonable limits.

Preservation of semen

Artificial insemination and egg transplantation. The practical application of artificial insemination in horses, cattle, sheep, and pigs was developed in Russia during the first decades of the 20th century. Semen was collected in an artificial vagina when the male mounted a female, or a dummy, and methods were developed for dilution of semen and its preservation for several days outside the body. More rapid progress became possible in 1950, when it was shown that bull semen could be deep-frozen at −79° C with solid carbon dioxide and later thawed without serious effect on fertility, provided that a certain amount of glycerol was added before freezing. Later, the use of liquid nitrogen made it possible to store semen at about −196° C. Calves have been produced from semen that has been frozen for more than 10 years, and it seems possible to increase the period of storage indefinitely. Theoretically, it should be possible to produce more than 100,000 calves per bull annually; 10,000 or more actually have been produced. In Denmark about 95 percent of the dairy cows are artificially inseminated; in England and Wales, about 70 percent; and in the United States, about 50 percent.

The greatest advantage of artificial insemination of dairy cattle from a genetic point of view is that the bulls can be progeny tested with much greater accuracy than in natural breeding, not only because the number of daughters is greater but also because the daughters are spread over many herds with different environmental conditions. A progeny test carried out in any one herd is valid for the conditions in that herd only. Furthermore, by artificial insemination the progeny test can be completed at least one year earlier, on average, than if the bulls were used in natural service.

Artificial insemination is practiced also on beef cattle, horses, sheep, pigs, and poultry, although on a small scale compared to its use with dairy cattle. The application of artificial insemination in pig breeding was delayed by difficulties in deep-freezing boar semen, but these difficulties have been overcome.

Polyovulation

By hormone treatment, production of many ova (polyovulation) can be induced in females. After artificial insemination, the fertilized eggs can be collected from the oviducts or uterus of the donor and transferred to the uteri of recipient females for development into normal fetuses. At the time of transfer, the recipient must be synchronized with the donor with regard to the sexual cycle. Many successful transplantations of fertilized eggs have been made in sheep, and some have been carried out in cattle and pigs. Theoretically, it is possible to harvest thousands of eggs from an individual female within a few years' time and to distribute these eggs to a large number of recipients, thereby multiplying the possibilities for propagation of superior females. To secure the eggs from the donor, however, and transfer them to other females is laborious and costly, even if it can be done without major surgery. Methods of freezing and storing eggs without harmful effects must be developed before the transplantation technique can be applied as a routine procedure in the breeding of farm animals.

The rate of genetic improvement. The rate at which genetic improvement can be carried out within a certain population depends on three factors:

1. The accuracy in estimating the breeding value of the individuals. This accuracy itself depends on the heritability of the trait or traits on which the selection is based. The value used may be based on the animal's own performance, as, for example, the milk yield of a cow, or it may be an index formed by a combination of information on breeding value derived from various sources such as pedigree, collateral relatives, and progeny.

2. The selection differential, which is defined as the difference between the index of the animals selected for breeding and the mean of the entire population or group to which the selected animals belong.

3. The length of the generation interval, defined as the average interval (in years) between the birth of the parents and the birth of their offspring used for breeding. On average, this interval for horses is about nine years, for cattle five, for sheep three and a half, for pigs two and a half, and for chickens one and a half. It is possible, however, to reduce these intervals quite considerably by planned breeding.

The overall rate of genetic improvement, or response to selection, is equal to the accuracy in selection multiplied by the selection differential and divided by the generation interval. In equation form this is expressed as: $Re = HS/Y$, in which Re is the response to selection, H is the heritability, S the selection differential, and Y the generation interval.

Response to selection

From this formula, it is evident that the rate of genetic improvement of the population can be increased by increasing the accuracy in choice of breeding animals, by increasing the selection differential, and/or by decreasing the length of the generation interval. The possibility of increasing the selection differential depends on the rate of reproduction. Pigs have a much higher reproductive rate than cattle, and therefore fewer animals are needed for breeding and a greater selection differential is possible. In dairy cattle it may be necessary to raise about 60 percent of all heifer calves for breeding, merely to keep the size of the herd constant. For bulls, however, the selection differential can be very high, especially when artificial insemination is used. The size of the population subjected to selection is also important. It has been calculated, for example, that when the number of performance-tested dairy cows in an artificial insemination unit increases from 2,000 to 20,000, it should be possible to increase the rate of genetic improvement for milk yield about 50 percent by means of efficient progeny testing and selection.

In most Western countries there was a pronounced improvement in many economically important traits of farm animals after World War II. In the United States, for example, the average yield of milk from milk-recorded cows increased from 9,425 pounds (4,275 kilograms) in 1955 to 12,209 pounds (5,538 kilograms) in 1967, an increase of 29.5 percent, or 2.27 percent per year; by 1980 an official test reported an average yield of 14,960 pounds (6,786 kilograms). For the Swedish red and white breed, the average milk yield increased from 9,473 pounds (4,297 kilograms) in 1960 to 11,094 pounds (5,032 kilograms) in 1969; *i.e.*, by 17.1 percent, or 1.71 percent per year. It has been estimated that the genetic improvement of this breed during the same period corresponded to about 1 percent per year, or more than half the actual rise in milk yield. It seems probable that the major part of the genetic improvement in this instance was due to a more efficient progeny-testing and selection program that had been started among the tested bulls in the mid-1950s. Similarly, in Danish pig-testing stations, the average daily gain in live weight increased from 23.9 to 24.6 ounces (678 to 697 grams) from 1955 to 1962, the length of carcasses increased from 36.9 to 37.8 inches (93.8 to 95.9 centimetres), and the backfat thickness decreased from 1.28 to 1.10 inches (3.26 to 2.80 centimetres). The modern broiler chick is an example of the success obtained by crosses between breeds that have been specialized for different lines of production without close inbreeding.

Limitation to selection

When there is a considerable amount of hereditary variation, it is possible to change a breeding population considerably in about five to 10 generations of intense selection. Sooner or later, the response to selection decreases, and ultimately a selection limit is reached. This may be due to an exhaustion of the genetic variation or, more likely, to a disturbed gene balance, especially if the selection is concentrated on one, or a very few, traits only, without considering the fertility and viability of the animals. The remedy in such a situation is either a cautious introduction of new genes from another population or deliberate cross-breeding to increase the genetic variation. In either case, selection in the gene-enriched population can start again. Another possibility is to relax the selection for a number of generations, giving the population time to recover, but this is a rather time-consuming process. (I.J.)

Livestock research and development. In the developed countries the trend toward feeding ruminant livestock with feed grains and forages grown on arable land is causing concern as an inefficient utilization of land in the face of the increasing need for grain as human food. More research effort, therefore, is likely to be directed toward increasing the yield of animal products from rangeland and permanent pasture. Large-scale nitrogen fertilization of pastures and other forages will improve their yield and nutritive value, and the practice will become justified as new forages are developed and the cost of nitrogen is lowered; in fact, world fertilizer consumption increased by some 75 percent in the 1970s. An alternative would consist of adding urea and ammonia salts to carbohydrates and forages as the sole source of nitrogen. That would increase the bacterial synthesis of protein in the rumen of cattle and sheep. Much urea is now fed to livestock; if its price trends low enough, it could be fed with forage whose protein content would thus be of less importance than its digestibility. Another possibility lies in the chemical treatment of high-lignin forages to increase digestibility. These techniques offer some hope for reduced consumption of grain by ruminants.

Large-scale fertilization of pastures

Dairy cows. The full potential of the dairy cow has not yet been realized. Worldwide, milk production per cow increased by 3 or 4 percent per year for more than 10 years until the early 1970s—largely from genetic improvements, better nutrition, and improved management—but has increased at a slower rate since. The effects of physiological and genetic limitations will probably not be felt until the year 2000. Meanwhile, breeding research and adoption of controlled environment housing will continue to increase milk production.

Beef cattle and swine. Productivity of beef cattle and swine is related to reproductive capacity, rate of growth, and the lean-meat percentage of the carcass. Of these factors, low reproduction rate is the most important. The percentage of mated beef cows who raise calves to maturity is 75 to 80 percent in the United States; 90 percent for The Netherlands and Denmark; but only 30 to 50 percent in developing countries. In the future, selection programs designed to increase the percentage of multiple births in beef cattle and swine will help to increase production efficiency. Reduction in losses both before and after birth can be realized by additional research. Progress in breeding and selection of swine for lean-meat carcasses has been achieved, a process that should be done also with beef cattle, because market surveys have shown preference for lean Holstein beef rather than the usual English breeds. The preference of beef feeders for crossbreeds is already well-established; heterosis (hybrid vigour) often results in a 5 to 20 percent increase over the best parental breed. Research on climate control at high temperature should result in improved production efficiency.

Efficiency in poultry production

Poultry. The efficiency of poultry production has undergone marked improvement. The potential limit for the laying hen is one two-ounce (56-gram) egg from each 2½-pound (1.1-kilogram) hen daily for one year, based on three pounds (1.4 kilograms) of feed per dozen eggs. The average hen, however, lays only about 230 eggs per year, weighs four pounds (1.8 kilograms), and requires four pounds of feed to produce a dozen eggs. One point of potential gain lies in causing the hen to lay eggs without shells, although public acceptance might be limited. The ultimate for feed conversion in the broiler is one pound (0.45 kilograms) of meat for every pound of feed utilized in a five-week growing period. The present conversion ratio is 2.2 pounds (one kilogram) feed for every pound of meat, utilized over a seven- to nine-week growing period. Increased productivity in poultry of the future will result from new genetic combinations and further improvements in environmental and management factors. One promising area for future research may be in exploration of performance as related to environmental conditions.

The future for livestock. The biological limits in livestock productivity have not been achieved in any class of farm animal. Fundamental research in biochemistry, endocrinology, environmental physiology, genetics, parasitology, microbiology, and disease has provided knowledge that will make progress possible. For example, swine have reached market weights of over 200 pounds (90 kilograms) in 120 days with little more than two pounds of feed per pound of gain. Some hogs have yielded loin eyes of nine square inches (58 square centimetres) and 50 percent of the carcass weight in ham and loin. Sows have farrowed more than 30 pigs in one litter. Knowledge of the endocrine system and its hormone production now makes it possible to synchronize estrus (heat), cause superovulation, and ultimately to control body composition. Fibre digestion efficiency in ruminants depends on the type of bacteria and protozoa in the rumen. By controlling these microbes, the quality of protein synthesized can be improved. There is reason to hope that in the fairly near future hogs will be marketed 100 days from birth and beef animals within six months; that each hen will produce two eggs a day; and that the beef cow will produce two calves per year. (R.E.S.)

COOPERATIVE AND GOVERNMENTAL PROMOTION OF ANIMAL BREEDING

In most countries in which animal breeding has reached a fairly high level, associations were formed long ago (beginning in Great Britain in the late 18th century) with the aim of promoting the development of existing breeds. At first the primary objectives of breeders' associations were to publish herdbooks and to lay down rules for registration of "purebred" animals, to arrange shows and fairs, and to work for the dissemination of the breeds at home and abroad. Later, these associations started performance testing or worked in close cooperation with other organizations developed for this purpose. In European cattle breeding there is a trend toward concentration into one organization of the various activities, such as performance and progeny testing, artificial insemination, and other services, among which herdbook registration may be only a minor detail. A similar trend has appeared also in the breeding of sheep, pigs, and fur animals. With regard to the breeding of animals for sport or as pets, traditional breeders' associations are, and probably will continue to be, of great importance.

Breeders' associations

Scientific research has been the foundation, and education the impelling force, in the accelerated development of animal breeding in the 20th century. Specialized research institutes and experimental stations, with cooperating agricultural colleges and extension divisions, have arisen in almost every country in which animal production is an important enterprise. Most information based on laboratory research and breeding experiments has arisen in the United States and Great Britain, but Denmark seems to have been the first country to organize an agricultural extension service that reached all levels of farming and animal husbandry.

Organizations have been established in several countries to promote animal science and production; for example, in the United States, the American Society of Animal Science and the American Dairy Science Association; in Great Britain, the British Society of Animal Production; and in Germany, Deutsche Gesellschaft für Züchtungskunde. In 1966 these national organizations formed the World Association for Animal Production, the major objective of which is to arrange periodic world conferences for the exchange and dissemination of knowledge in the field of animal science. (I.J.)

Animal nutrition

Animals in general require the same nutrients as humans. (This section is concerned primarily with feed for livestock and poultry.) Some feeds, such as pasture grasses, hay and silage crops, and certain cereal grains, are grown specifically for animals. Other feeds, such as sugar-beet pulp, brewers' grains, and pineapple bran, are by-products remaining after a food crop has been processed for human use. Surplus food crops, such as wheat, other cereals, fruits, vegetables, and roots, may also be fed to animals. In this way such surpluses are converted into meat, milk, and eggs for the human diet.

History does not record when dried roughage or other stored feeds were first given to animals. Most early records refer to nomadic people who, with their herds and flocks, followed the natural feed supplies. When animals were domesticated and used for work in crop production, some of the residues were doubtless fed to them.

Preservation of green forages such as beet leaves and corn (maize) plants by packing them in pits in the earth has long been practiced in northern Europe. The idea of making silage as a means of preserving and utilizing more of the corn plant was gradually developed in Europe and brought from France to the United States in the 1870s. When the mature, dried corn plant was fed to cattle in the winter much of the coarse stem was wasted, but when it was chopped and ensiled (made into silage) everything was eaten. The first effort to evaluate feeds for animals on a comparative basis was apparently made by Albrecht Thaer (1752–1828), in Germany, who developed "hay values" as measures of nutritive value of feeds. Tables of the value of feeds and of the requirements of animals in Germany followed and were later used in other countries. Present-day knowledge represents an expansion and improvement of these early efforts.

BASIC NUTRIENTS AND ADDITIVES

The basic nutrients that animals require for growth, reproduction, and good health include carbohydrates, protein, fat, minerals, and vitamins. The energy needed for growth and activity is derived primarily from carbohydrates and fats. Protein may also supply energy, however, if other sources are not adequate or if it is supplied in great excess above the needs of the body.

Animals need a source of energy to sustain life processes within the body and for muscular activity. When the energy intake of an animal exceeds its requirements, the surplus is stored as body fat, which can be utilized later if the energy consumed in food is not adequate.

Proteins. All animals require a small amount of protein for the daily repair of muscles, internal organs, and other body tissues. For immature animals, protein is also needed for growth of the muscles and other parts of the body. Since milk, eggs, and wool contain much protein, additional amounts are needed in the food of animals producing these.

Proteins are composed of more than 20 different amino acids, which are liberated during digestion. Animals with simple stomachs, including humans, monkeys, swine, poultry, rabbits, and mink, require correct amounts of the following 10 essential amino acids daily: arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, trytophan, and valine. In addition to these, poultry need glycine and glutamic acid for growth. High-quality protein supplied by eggs, milk, fish meal, meat by-products, and soybean meal contains correct amounts of the essential amino acids. Poor-quality protein, such as that in corn grain (maize), contains too little of one or more essential amino acids. Feeds having poor-quality proteins are made useful by blending them with other feeds that supply the lacking amino acids.

Role of ruminants

The quality of the protein in the food is of little importance to ruminants, including cattle, sheep, goats, and the other animals that have four stomachs, because the bacteria that aid in the digestion of food in the rumen (first stomach) use simple nitrogen compounds to build proteins in their cells. Further on in the digestive tract the animals digest the bacteria. By this indirect means, ruminants produce high-quality protein from a food that might originally have contained poor protein, or from urea (a nitrogen compound). Very young ruminants, such as calves, lambs, and kids, however, need good-quality protein until the rumen develops sufficiently for this bacterial process to become established.

Carbohydrates and fats. Most animals get energy from carbohydrates and fats, which are oxidized in the body. These yield heat, which maintains body temperature, furnishes energy for growth and muscle activity, and sustains vital functions. Animals need much more energy (and more total feed) for growth, fattening, work, or milk production than simply for maintenance.

The less complex carbohydrates (sugars and starches) are readily digested by all animals. The complex carbohydrates (cellulose, hemicelluloses) that make up the fibrous stems of plants are broken down by bacterial action in the rumen of cattle and sheep or in the cecum of rabbits and horses. Such complex carbohydrates cannot be digested by men, or, to any appreciable extent, by dogs, cats, birds, or laboratory animals. Thus, ruminants and some herbivorous animals obtain much more of the energy-giving nutrients from the carbohydrates of plants than the simple-stomached carnivores and omnivores, for which fibrous materials have little or no energy value.

Fat in feeds has a high nutritive value because it is highly digestible, and because it supplies about two and one-quarter times as much energy as starch or sugar. While fat has high nutritive value, it can be replaced by an equivalent amount of digestible carbohydrates in the food, except for small amounts of essential fatty acids. Very small amounts of the unsaturated fatty acid linoleic, contained in some fats, are necessary for growth and health. Usual animal feeds, however, supply ample amounts of this acid unless it has been removed by processing.

Minerals. Minerals essential for animal life include common salt (sodium chloride), calcium, phosphorus, sulfur, potassium, magnesium, manganese, iron, copper, cobalt, iodine, zinc, molybdenum, and selenium. The last six of these are poisonous to animals if excessive amounts are eaten.

All farm animals generally need more common salt than is contained in their feeds, and they are supplied with it regularly. Of the other essential minerals, phosphorus and calcium are most apt to be lacking, because they are heavily drawn upon to produce bones, milk, and egg shells. Good phosphorus supplements are bone meal, dicalcium phosphate, and defluorinated phosphates. Egg shells are nearly pure calcium carbonate. Calcium may readily be supplied by ground limestone, ground shells, or marl that is high in calcium.

Losses caused by goitre

Small amounts of iodine are needed by animals for the formation of thyroxine, a compound containing iodine, secreted by the thyroid gland. A serious deficiency of iodine may cause goitre, a disease in which the thyroid gland enlarges greatly. In certain regions goitre has caused heavy losses of newborn pigs, lambs, kids, calves, and foals. Goitre can be prevented by supplying small amounts of iodized salt to the mother before the young are born.

In some areas, soil and forage are deficient in copper and cobalt, which are needed along with iron for the formation of hemoglobin, the oxygen-carrying pigment of the red blood cells. In these areas, farm animals may suffer from anemia unless the deficiency is corrected by means of a suitable mineral supplement.

Iron, used in hemoglobin formation, is amply supplied in most animal feeds, except milk. The only practical problem with iron deficiency occurs in young suckling pigs before they start to consume other feeds in addition to milk.

Though manganese is essential for animals, the usual rations for all farm animals, except poultry, supply sufficient quantities. A lack of manganese may cause the nutritional disease of chicks and young turkeys called slipped tendon (perosis) and also may cause failure of eggs to hatch. Normal rations for swine are often deficient in zinc, especially in the presence of excess calcium. Adding 100 parts per million of zinc carbonate cures zinc-deficiency symptoms, which include retarded growth rate and severe scaliness and cracking of the skin (parakeratosis). A trace of selenium is necessary for normal health of animals; excessive amounts found in forages in some regions poison animals and may cause death. To furnish both calcium and phosphorus, livestock may be allowed free access to such a mixture as 60 percent dicalcium phosphate and 40 percent common salt. Trace mineralized salt is used when copper or cobalt may be deficient. Animals are given access to common salt separately, so they will not be forced to eat more of the other minerals than they require to get the amount of salt they need.

Vitamins. Known vitamins include A, C, D, E, and K, and the B group: thiamine, riboflavin, niacin, pantothenic acid, choline, biotin, folic acid, and vitamins B_6 and B_{12}.

Vitamin A, the one most apt to be lacking in livestock feeds, is required for growth, reproduction, milk production, and the maintenance of normal resistance to respiratory infections. All green-growing crops are rich in carotene, which animals can convert into vitamin A. Vitamin A supplement is added to animal rations to ensure a supply when they are not on good pasture.

Vitamin D in hay

Vitamin D enables animals to use calcium and phosphorus; a deficiency causes rickets in young growing animals. The ultraviolet rays of sunlight produce vitamin D from the provitamin in the skin. Field curing of hay develops vitamin D through the action of the sunlight on ergosterol in the hay crops. Certain fish oils are very rich in vitamin D. Livestock that are outdoors in the sunlight much of the time have a plentiful supply of vitamin D. Under winter conditions in cold regions, cattle, sheep, and horses ordinarily get ample amounts from the hay they are fed; laboratory animals may be deficient unless a supplement is added.

The vitamin B group is not important in the feeding of cattle, sheep, and other ruminants because the bacteria in the rumen synthesize these vitamins. Very young calves, poultry, swine, and other simple-stomached animals require the B vitamins in their diets. Of these, riboflavin, niacin, pantothenic acid, and vitamin B_{12} are most likely to be deficient in ordinary feeds; special supplements are needed by pigs, poultry, and laboratory animals. Choline may also be deficient in poultry feeds.

Vitamin E is necessary for normal hatching of eggs. It plays a role along with selenium in preventing muscle stiffness and paralysis (dystrophy) in lambs, calves, and chicks under certain conditions. Vitamin C, which prevents scurvy in humans and guinea pigs, can be synthesized in the bodies of other animals and need not be supplied in their food. Vitamin K is synthesized by bacteria in the intestinal tract; a dietary supply is usually not important.

Antibiotics and other growth stimulants. Since about 1950, antibiotics have been added to diets of growing animals because they increase the rate of growth and decrease death loss. Those most commonly used are chlortetracycline, oxytetracycline, bacitracin, and penicillin. An antibiotic helps to overcome the growth-depressing effects of an inadequate diet or of imperfect management practices, but its effectiveness differs among animal species.

Diethylstilbestrol, testosterone, progesterone, estradiol, and dienestrol in various combinations are administered orally or subcutaneously to stimulate growth of cattle and sheep for meat production.

COMPOSITION AND VALUATION OF FEEDS

The usual chemical analyses of feeds provide information on the amount of dry matter, protein, fat, fibre, and ash contained in the feed. Energy value, mineral elements, and vitamins are also determined; these values are included in complete tables of feed composition.

Animal protein requirements

Determination. Digestion and balance experiments measure the degree to which the various components of a feed are absorbed and retained by the animal body. Protein requirements are expressed as the amounts of digestible protein needed for growth or other body functions. The amounts of energy needed are measured as digestible energy (DE), metabolizable energy (ME), net energy (NE), or total digestible nutrients (TDN). The total gross energy value of a feed is the amount of heat liberated when it is burned in a bomb calorimeter. Only a part of this energy is available to the animal because some passes through the body without being digested. Furthermore, some of the DE is not utilized but is excreted in the urine as urea. There is a further energy loss from the ME as heat of fermentation and as gas produced by bacteria in the digestive tract. This loss is appreciably greater in ruminants than in pigs, chickens, or other nonruminants. The work of eating, digesting, and metabolizing food may also be subtracted from the food energy, resulting in the NE, or useful energy value of a food. The TDN value of a feed represents the sum of the digestible protein, digestible fat × 2.25, digestible nitrogen-free extract, and digestible fibre. This measure is less useful than NE because it considers neither the fermentation and heat losses during digestion and metabolism nor the fact that energy is utilized more efficiently for maintenance or milk production than for growth and fattening.

Optimization of nutrient-cost ratio. Feed costs vary widely from season to season; it is often possible for producers to realize substantial savings by wise selection of the feed ingredients used to formulate complete rations. It is much easier for large commercial feed companies with operations in different regions to take advantage of low costs than it is for individual relatively small-scale livestock producers.

Least-cost programming of feed mixtures makes it possible to use electronic computers for selecting the correct amounts of the lowest-cost feed ingredients that will fully satisfy the nutrient requirements of a specific type of animal at a particular stage of development. The system has successfully formulated highly palatable rations that yield maximum production at lowest cost. As in other areas of agriculture, the large-scale producer, with the ability to purchase and operate advanced systems, has an economic advantage.

BASIC TYPES OF FEEDS

Animal feeds are classified as follows: (1) concentrates, high in energy value, including (*a*) cereal grains and their by-products (barley, corn [maize], oats, rye, wheat), (*b*) high-protein oil meals or cakes (soybean, cottonseed, peanut [groundnut]), (*c*) by-products from processing of sugar beets, sugarcane, and (*d*) animal and fish by-products; (2) roughages, including (*a*) pasture grasses, (*b*) hays, (*c*) silage, (*d*) root crops, and (*e*) straw, stover (stalks). The composition of a few of the most commonly used feeds is shown in Tables 1 and 2.

Concentrate foods. *Cereal grains and their by-products.* In the agricultural practices of North America and northern Europe, barley, corn (maize), oats, rye, and sorghums are grown almost entirely as animal feed, although small quantities are processed for human consumption as well. These grains are fed, whole or ground, either singly or mixed with high-protein oil meals or other by-products, minerals, and vitamins, to form a complete feed for pigs and poultry or an adequate dietary supplement for ruminants and horses.

The production of grains is seasonal because of temperature or moisture conditions or a combination of both. It is necessary to produce a full year's supply during the limited growing season. The grain is dried to prevent sprouting or molding; the grain is then stored in containers or buildings where insects and rodents cannot destroy it. It is generally desirable to store more than a year's supply of the grains to be used as feed, because crop failures sometimes occur.

Grainfeed storage

Table 1: Concentrates Commonly Used as Animal Feeds

type of concentrate	composition (%)					
	dry matter (total)	protein	fat	fibre	ash	NFE*
Barley	88.6	12.0	2.1	7.4	3.3	63.8
Beans (*Phaseolus* species)	89.0	23.0	1.2	4.1	3.9	56.8
Bone meal, steamed	95.0	12.1	3.2	2.0	71.8	5.9
Brewers' grains	92.0	25.9	6.2	15.0	3.6	41.3
Brewers' yeast	93.0	44.6	1.1	3.0	6.4	37.9
Citrus pulp	90.0	6.6	4.6	13.0	6.0	59.8
Coconut meal	93.0	20.4	6.6	12.0	6.9	47.1
Corn	86.5	9.1	4.0	1.8	1.2	70.4
Corn distillers' grains	91.6	29.1	8.9	11.5	3.1	39.0
Corn ears (corn and cob meal)	87.0	8.1	3.2	8.0	1.6	66.1
Corn gluten feed	90.0	25.3	2.4	8.0	6.3	48.0
Cottonseed, whole	92.7	23.1	22.9	16.9	3.5	26.3
Cottonseed meal	94.0	41.0	4.3	12.0	6.2	30.5
Fish meal	92.0	63.2	4.4	—	21.7	27.0
Hominy feed	90.6	10.7	6.5	5.0	2.5	65.9
Linseed meal	91.0	35.3	5.2	9.0	5.6	35.9
Meat and bone meal	94.0	50.6	9.5	—	29.1	48.0
Milk, dried skimmed	94.0	33.5	0.9	—	7.6	26.3
Molasses, cane	75.0	3.2	0.1	—	8.1	63.6
Oats	91.0	12.1	4.8	12.0	3.2	58.9
Palm-kernel meal	91.4	19.2	6.7	11.9	3.9	49.7
Peanut meal	92.0	47.4	1.2	13.0	4.5	25.9
Pineapple bran or pulp	88.6	4.2	1.6	18.4	2.6	61.8
Poultry waste	93.1	52.1	13.6	—	8.5	18.9
Rapeseed meal	93.6	37.1	6.3	13.7	6.0	30.5
Rice, grain	89.0	7.3	1.9	9.0	4.5	66.3
Rice bran	91.0	13.5	15.1	11.0	10.9	40.5
Rye	89.0	11.9	1.6	2.0	1.7	71.8
Safflower meal	91.0	19.7	6.0	31.0	3.7	30.6
Sesameseed meal	93.0	47.9	5.1	5.0	9.3	25.7
Sorghum	88.0	10.3	2.6	2.1	1.9	71.1
Soybean hulls	91.3	12.5	2.1	35.5	4.6	36.6
Soybean meal	89.8	50.9	0.8	2.8	5.6	29.7
Soybean seed	90.0	37.9	18.0	5.0	4.6	24.5
Sugar-beet pulp	91.0	9.1	0.6	19.0	3.6	58.7
Wheat	89.0	12.7	1.7	3.0	1.6	70.0
Wheat bran	89.0	16.0	4.1	10.0	6.1	52.8
Wheat-germ meal	90.0	26.2	10.9	3.0	4.3	45.6
Wheat middlings	89.0	18.0	3.6	2.0	2.5	62.9
Whey, dried	94.0	13.8	0.8	—	9.7	69.7

*NFE = nitrogen-free extract.

High-protein meals. Vegetable seeds produced primarily as a source of oil for human food and industrial uses include soybeans, peanuts (groundnuts), flaxseed, cottonseed, coconuts, oil palm, and sunflower seeds. After these seeds are processed to remove the oil, the residues, which may contain from 5 percent to less than 1 percent of fat and 20 to 50 percent of protein, are marketed as animal feeds. Cottonseed and peanuts have woody hulls or shells, which are generally removed before processing—if the hulls or shells are left intact, the resulting by-product is higher in fibre and appreciably lower in protein and energy value.

These feeds are used as supplements to roughages or cereal grains and other low-protein feeds to furnish the protein needed for efficient growth or production. The supplement chosen for a particular ration depends largely upon the cost and availability of supply.

By-products of sugar beets, sugarcane. From the sugar-beet industry come beet tops, which are used on the farm either fresh or ensiled, and dried beet pulp and beet molasses, which are produced in the sugar factory. Cane molasses is a residue from cane-sugar manufacture. These are all palatable, high-quality sources of carbohydrates. Sugarcane bagasse (stalk residue) is fibrous, hard to digest, and of very low feed value. In some European countries fodder beets and some other roots are grown as animal feed. Citrus molasses and dried citrus pulp, which are generally available at low cost as by-products of the citrus-juice industry, are often used as high-quality feeds for cattle and sheep.

Other by-product feeds. By-products or residues from commercial processing of the cereal grains to produce human food supply large quantities of animal feeds. The largest group of these comprises feeds derived from the milling of wheat in the production of flour including wheat bran, wheat middlings, wheat-germ meal, and wheat-mill feed. In some areas bakery wastes, such as stale and left-over bread, rolls, and various pastry products, are ground and used as filler or feed for pets and farm animals. Rice bran and rice hulls are obtained in similar fashion from the mills that polish rice for human food. Corn gluten feed, corn gluten meal, and hominy feed are produced as by-products from the manufacture of starch for industrial and food uses.

Brewers' grains, corn-distillers' grains, and brewers' yeast are useful animal feeds and are collected from the dried residues of the fermentation industries that produce beer and distilled spirits. Waste products from pineapple-canning plants include pineapple bran or pulp and the ensiled leaves from the plant. By-products from the abattoirs and meat-packing plants that process animals into meat include such feeds as meat and bone meal, tankage, meat scraps, blood meal, poultry waste, and feather meal. Dried skim milk, dried whey, and dried buttermilk are feed by-products from the dairy industry. Various types and qualities of fish meals are produced by the fish-processing plants. These feeds contain 50 percent or more of high-quality protein and the mineral elements calcium and phosphorus. Steamed bone meal is particularly high in these important minerals.

Bone and fish meals

Roughages. *Pasture.* Pasture grasses and legumes, both native and cultivated, are the most important single source of feed for cattle, horses, sheep, and goats. During the growing season they furnish most of the feed for these animals at a cost lower than for feeds that need to be harvested, processed, and transported. Hundreds of different grasses, legumes, bushes, and trees are acceptable as feeds for grazing animals. The nutritive value of the cultivated varieties has been studied, but information is incomplete for many of those that occur naturally. The composition of some of the forage crops most widely used is shown in Table 2.

Hay. Hay is produced by drying grasses or legumes when they approach the stage of maximum plant growth and before the seed develops. This stage has been shown to give maximum yields of digestible protein and carbohydrates per unit of land area. The moisture content must be reduced to 22 percent or less to prevent molding, heating, and spoilage during storage. Legume hays, such as alfalfa and clovers, are high in protein, while the grasses (such as timothy and Sudan grass) are lower in protein but vary considerably depending upon the stage of maturity and level of nitrogen fertilization applied to the crop. Stored hay is fed to animals when sufficient fresh pasture grass is not available.

Legume and grass hays

Silage. Silage is made by packing immature plants in a storage container to exclude the air and allow fermentation to develop acetic and other acids, which preserve the moist feed. Storage may be in upright tower silos or in trenches in the ground. Best quality silage results when the forage is ensiled with a moisture content of 50 to 65 percent. Lower moisture levels can cause difficulty in obtaining sufficient packing to exclude air and may result in molding or other spoilage. Too high a moisture content causes nutrient losses by seepage and results in the production of excessively acid, unpalatable silage. Ensiled forage can be stored for a longer period of time with lower loss of nutrients than dry hay. The nutritive value of silage depends upon the type of forage ensiled and how successfully it has been cured. Corn (maize), sorghums, and grasses, and sometimes leguminous forages, are used in making silage.

Root crops. These are used less extensively as animal feed than was true in the past, for economic reasons. Mangels, rutabagas, cassava, and sometimes surplus potatoes are used as feed. As shown in Table 2, they are lower in dry-matter content than are most of the other feeds listed. They are relatively low in protein also and provide mostly energy.

Table 2: Roughages Commonly Used as Animal Feeds

type of roughage	composition (%)					
	dry matter (total)	protein	fat	fibre	ash	NFE*
Dry roughages						
Alfalfa hay	90.0	16.6	2.0	26.8	8.5	36.1
Berseem	90.6	13.4	3.1	24.4	11.0	38.7
Bromegrass hay	92.8	5.4	2.8	31.7	7.6	45.3
Clover hay, crimson (*Trifolium* species)	87.4	14.8	2.0	28.1	8.3	34.2
Corn cobs	90.4	2.5	0.5	32.4	1.5	65.2
Corn fodder	87.2	5.1	1.0	32.4	6.2	42.5
Cottonseed hulls	90.3	3.9	1.4	42.9	2.5	39.6
Lespedeza hay	93.0	14.6	3.7	28.6	5.5	40.6
Oat hay	88.2	8.1	2.7	27.3	6.6	43.5
Oat straw	90.1	4.0	1.9	36.9	7.4	39.9
Peanut hay, without nuts	90.6	10.0	3.2	23.6	9.6	44.2
Rice hulls	92.0	3.0	0.8	40.7	19.1	28.4
Rice straw	92.5	3.9	1.4	33.5	14.5	39.2
Sorghum, without heads	85.1	4.5	1.8	27.7	8.2	42.9
Soybean hay	89.2	14.5	2.7	28.6	7.2	36.2
Timothy hay	87.7	7.6	2.3	29.1	5.4	43.3
Wheat straw	92.6	3.9	1.5	37.0	8.3	41.9
Green roughages						
Alfalfa	21.1	4.3	0.5	5.5	2.0	8.8

Straw and hulls. Quantities of straws remaining after wheat, oats, barley, and rice crops have been harvested are used as feed for cattle and other ruminants. The straws are low in protein and very high in fibre; digestibility is low. Straw is useful in maintaining mature animals during periods of shortage of other feeds, but it is too low in quality to be satisfactory for long periods without being supplemented with other feeds to supply the protein, digestible energy, and minerals needed for growth and production. Treatment of straw with alkali markedly increases the digestibility of the cellulose, augmenting its value as a source of energy for animals.

Corncobs, corn stalks, cottonseed hulls, and rice hulls can also be used as sources of fibre in ruminant rations. Rice hulls are lower in value, while the others are similar to straw.

(J.K.L.)

CROP-FARMING

Cereal farming

Cereals, or grains, are members of the grass family cultivated primarily for their starchy seeds (technically, dry fruits), which are used for human food, livestock feed, and as a source of industrial starch. Wheat, rice, corn (maize), rye, oats, barley, sorghum, and some of the millets are common cereals.

The cultivation of cereals varies widely in different countries and depends partly upon the degree of economic development. The condition and purity of the seed is receiving increasing attention. Other factors include the nature of the soil, the amount of rainfall, and the techniques applied to promote growth. In illustrating production problems, this section will use wheat as the example. For information on the cultivation of other cereal crops such as rice, see articles on the individual crops in the *Micropædia.* For information on the food value and processing of cereals, see the article FOOD PROCESSING.

CULTIVATION OF WHEAT

Wheat can be cultivated over a wide range of soils and can be successfully grown over large portions of the world, ranging in altitude from sea level to over 10,000 feet. Annual rainfall of 10 inches (254 millimetres) is generally considered the minimum, and the soil should be sufficiently fertile. (Barley can be grown in soil less fertile than that required for wheat.) Soil benefits from a good humus content (partially decayed organic matter), and chemical fertilizers are also helpful.

Importance of seed purity

Purity of the seed is important. The seed wheat (or other cereal seeds) must be true to its particular variety and as free as possible from foreign seeds. Seeds are frequently cleaned to avoid contamination by other seed crops. Modern cleaning methods employ such devices as oscillating sieves or revolving cylinders. Seed obtained with a combine harvester is often unsuited for use as seed wheat without preliminary treatment. Spring and winter varieties exist for both wheat and barley. Winter varieties generally produce better crops. Winter wheat should form a good root system, and the plant should begin to form new shoots before the cold weather sets in; winter wheat is likely to have more tillers than spring wheat.

The rate of sowing varies from 20 pounds per acre (22.5 kilograms per hectare) upward. Depth of sowing, usually one to three inches (2.5 to 7.5 centimetres), can be less in certain areas.

Breeding. Wheat and other cereals are self-fertilized. The pollen carried by the stamen of a given flower impregnates the pistil (stigma and ovary) of the same flower, enabling the variety to breed true. Wheat flowers are grouped in spikelets, each bearing from two to nine flowers, or florets. To produce new varieties by cross-fertilization, the cereal breeder artificially transfers the stamen from one variety to the flower of another before self-fertilization takes place. The production of a sufficient supply of the new type of seeds for sowing is time-consuming and expensive, but it allows new varieties to be evolved, retaining the desirable characteristics from each parent. For example, especially in the United Kingdom and Australia, varieties of the wheat that yield well often produce flour of poor baking quality; proper selection of parent plants permits new varieties to be produced that yield well and still possess good baking qualities.

Other reasons for developing new varieties include resistance to rust (fungus; see below) and other diseases, resistance to drought, and development of stronger and shorter straw to make harvesting easier.

Seedbed preparation. Various types of plowing machinery and other implements are employed to render the soil more suitable for seed wheat planting. The equipment used depends upon such factors as the climate, the nature of the ground, and the rainfall. Tillage is the process of preparing soil for cultivation purposes. The practices used and the implements employed vary considerably. Serious soil erosion may require special procedures to maintain clods and plant residues in the soil.

Tillage

In North America it is normal practice to grow wheat on the same ground for as long as sufficiently clean crops are produced, but eventually the ground must rest fallow for a year. The moisture of the land at the time of sowing is an important factor. The ancient procedure of growing legumes occasionally to improve the soil is still common in Europe, though less so in North America. Fertilization of the ground is useful to increase the crop yield, but it does not generally increase the protein content of the crop. In the large collective state farms of the Soviet Union, huge harrows set with spikes or teeth are employed, as well as the disk cultivating plow set with disks that break up the soil; the scarifier, a machine that pulverizes the soil, is popular in Australia.

PLANT PROTECTION

Winter crops are frequently disturbed by frost, and the ground must then be rolled in the spring to consolidate the soil around the roots. If soil has become crusted by heavy rains followed by surface drying, the crop is usually harrowed in the spring to aerate the soil and kill young weeds. Although all of the required mineral nutrients may be added to the soil at the time of sowing, sometimes only part of the nitrogenous fertilizers is added at that time, and the remainder is applied to the growing crop in the form of a top dressing. In the cultivation of spring wheat all of the fertilizer is usually added before or at sowing time, but sometimes a small portion is reserved for later.

Weeds. Weeds present difficulties, as they compete with cereal crops for water, light, and mineral nutrients. The infestation of annual seeds planted in a field may cause many weeds in that field for successive years. Charlock or wild mustard, wild oats, crouch grass, and other common weeds are disseminated by wind, water, and birds.

Insects. In addition to weeds, wheat and other cereals are seriously affected by insects.

Grasshoppers and locusts

Grasshoppers and locusts cause immense damage. Spraying from airplanes with chemicals such as gamma BHC, Dieldrin, chlordane, or Toxaphene is effective; on small farms grasshopper control is often accomplished by weed killers such as MCPA (2-methyl-4-chlorophenoxyacetic acid) and 2,4-D (2,4-dichlorophenoxyacetic acid).

The eggs of click beetles are laid in the soil, and the larvae, called wireworms, live underground for some years, feeding on the roots and stems of the young plants (particularly slow-growing plants). To combat such damage, chemical seed dressing is used together with nitrogenous fertilizers. Other measures use such chemicals as gamma BHC (Lindane) or Dieldrin.

Aphids attack many plants, and the wheat aphid, or greenbug, causes damage throughout the world. Preventive action includes preparing a good seedbed, sufficient fertilization, and early sowing.

The wheat stem sawfly (*Cephus cinctus*) is found in many parts of the world. Infested wheat shows fallen straw filled with a fine sawdust material harbouring brown-headed larvae that pass the winter in the base of the wheat straw; the wasplike adult insect emerges around June. The females thrust their eggs into the upper plant tissues, and the larvae feed within the stem toward the base until the stem collapses. Varieties of Manitoba wheat such as Rescue and Chinook are reasonably resistant to the pest, and thorough plowing in of the infested stubble is generally effective. Certain crops, such as brome grass, attract this pest and may be grown on the borders of wheat crops to distract the pests away from the wheat. The hessian fly (*Mayetiola,* or *Phytophaga, destructor*), resembling the mosquito, attacks the stems of wheat, barley, and rye. Late wheat usually escapes damage from this pest.

Many wheats in central Europe and the Middle East have shown evidence of attacks from the wheat bug (*Weizenwanze,* or *blé punaisé*). The two main varieties are the *Aelia* and the *Eurygaster.* The eggs are laid in the spring, and the new generation appears in the summer. When the wheat is harvested, the bugs leave the stubble field and migrate to nearby foliage for the winter. To thrive and multiply, wheat bugs require sun, warmth, and absence of pronounced dampness.

Gluten damage

The wheat bugs puncture the grain and introduce by means of their saliva an enzyme that profoundly modifies the nature of the gluten. The puncture mark can be seen on the grain, usually surrounded by a yellow patch, and sometimes the grain is shrivelled. The main damage comes from attacks on the grain just before maturity. Although the insects leave, the damaged grain remains normal in size and remains in the wheat mixture sent to the mill.

The gluten of flour produced from infected wheat rapidly loses its cohesion upon standing in water, eventually disintegrating completely. Strong wheats resist wheat-bug attack better than soft, weak wheats do. There is little change in strong baking flours if only 1 percent of the grains are affected; in flour from soft wheats, the damage with even 1 percent to 2 percent of the grains affected can make the baking quality unacceptable. Countries in which the crop is affected by this pest include Romania, Hungary, Greece, and Morocco.

Fungus diseases. In the fungus group known as rust, the chief damage is caused by black rust (*Puccinia graminis*). Because this fungus spends part of its life on cereals and part on the barberry bush, these bushes are often eradicated near wheat fields as a preventive measure. Black rust causes cereal plants to lose their green colour and turn yellow. The grain produced is small, shrivelled, and has a low weight per bushel. New wheats, more resistant to rust, are being introduced.

In many countries wheat is attacked by smut. Stinking smut (or bunt) is fairly common in the United Kingdom. Malformed grains are produced, filled with black spores that spread over noninfected grain and give off a "fishy" smell.

Ergot (*Claviceps purpurea*) is a fungus more often attacking rye than wheat. It forms a dark purple mass, larger than the grain, containing 30 percent fatty material and the alkaloid ergotoxine, which has a profound pharmacological effect on the human and animal body and can produce abortion. Much of this fungus is likely to be removed in the mill screen room, and the clean grain sent on to the mill should contain not more than 0.04 percent of this fungus and preferably less.

HARVESTING

In the developed countries, harvesting of wheat and often other cereals is done principally by the combine harvester, though in the developing countries the ancient scythe, sickle, and flail are still widely used.

The McCormick reaper

The mechanical ancestor of today's large combines was the McCormick reaper, introduced in 1831 and followed by self-raking reapers that delivered the cut grain in bunches on the ground to be bound by hand. In 1843 a "stripper" was brought out in Australia that removed the wheat heads from the plants and threshed them in a single operation. Threshing machines were powered first by men or animals, often using treadmills, later by steam and internal-combustion engines. The modern combine harvester, originally introduced in California about 1875, came into wide use in the United States in the 1920s and '30s and in the United Kingdom in the 1940s. In 1940 the self-propelled combine was introduced. The combine cuts the standing grain, threshes out the grain from the straw and chaff, cleans the grain, and discharges it into bags or grain reservoirs. Other crops also can be worked by adaptations of the machine, and the reduction in harvesting time and labour is striking; in 1829 harvesting one acre of wheat required 14 man-hours, while the modern combine requires less than 30 minutes. In the early part of the 19th century harvesting a bushel of wheat required three man-hours' work; today it takes five minutes.

For satisfactory results, crops should not be too damp and should be reasonably ripe. If the grain contains over 14 percent moisture, as often happens in the United Kingdom and other European countries, it must be dried after harvesting under controlled conditions to avoid damage to the gluten. Rice can be combine-harvested, but because of its high moisture content (approaching 20 percent) it must be immediately dried.

GRADING

Wheat is an important commodity in international commerce, and many attempts have been made to ensure reliability in grading. In North America excellent grading allows the buyer to ascertain the type and standard of wheat acquired. Canada has statutory grades for most of its wheats. For wheat moving overseas from the terminal positions, standard export samples are used in grading.

Flour from an inferior grade is not automatically weaker than the top grade.

In the U.S. much of the wheat is officially graded, notably the hard spring and the hard winter wheats. Grading also takes place in Argentina and Australia, although it is not usually as precise as in North America. In many countries there is little commercial grading of wheat, and the buyer relies on his own testing and assessments of wheat arrivals. In Australia "fair average quality" (FAQ) indicates wheat not obviously unsatisfactory visually but takes no account of the baking strength and the character of the flour yielded. In recent years, however, considerable improvement in grading has taken place, especially when hard strong varieties are sold, as in the case of special high-protein Australian wheat from northwestern New South Wales and from Queensland.

In the U.K. there is no official wheat or barley grading as in North America. Barley is bought on appearance or by named variety. This is largely true in much of Europe, although the former Soviet Union introduced a grading system for wheat covering red spring, durum, white spring, red winter, and white winter, with special subclasses based on factors such as vitreousness, colour, and weight.

STORAGE

Cereal storage has been of concern from the earliest times; references are made to it in the Bible. Harvest variations from season to season produced carryover requiring storage, a problem that grew with increasing populations and developing commerce. The diary of Samuel Pepys (1633–1703) records the destruction of the wheat storehouses in the Great Fire of London (1666) and mentions the existence of these storehouses from the reign of Henry VIII (ruled 1509–47). With modern international cereal trade, huge silos are now found at the main points of export and at the docks of importing countries. In the major exporting countries silos at the country elevators feed the terminal silos; inefficient storage at any of these points makes the cereals highly vulnerable to insects and rodent attack. In certain regions, such as India, losses have amounted to 40 percent of the crop.

Grain respiration

A constant danger also lies in the respiration of the grain. If the moisture content of grain is low (10–12 percent), a rise in temperature resulting from respiration is unlikely; but if the bulk is large and the moisture content high (over 16 percent), the heat may not be dissipated, causing the temperature to rise and further increase the rate of respiration. Consequently, cereal stocks are turned over to ventilate the grain and to keep the temperature low. The problem also occurs in the holds of ships; much litigation has resulted from the arrival of hot and damaged cargoes.

Molds and fungi are other sources of spoilage that have received extensive study in recent years. Cleaning processes remove as much as possible of external molds before storage, but in hot countries, particularly, the problem remains serious. Under primitive conditions the habits and development of communities depended largely on their skill in storing grain.

Heat is also frequently a cause of loss of weight, loss in milling value, and loss in food value through its provision of a favourable environment for such insects as the grain weevil (*Sitophilus granarius*), the rice and maize weevils (*S. oryzae*), the lesser grain borer (*Rhizopertha dominica*), and the angoumois grain moth (*Sitotroga cerealella*). These are all endosperm borers. Among the grain germ eaters are the rust-red grain beetle (*Cryptolestes ferrugineus*), the saw-toothed grain beetle (*Oryzaephilus surina-

mensis), the khapra beetle (*Trogoderma granarium*), and the warehouse moth (*Ephestia elutella*).

Secondary pests include the mill pest known as the Mediterranean flour moth (*Anagasta kuehniella*), the confused flour beetle (*Tribolium confusum*), the rust-red flour beetle (*T. castaneum*), the flat grain beetle (*Cryptolestes pusillus*), the broad-horned flour beetle (*Gnathocerus cornutus*), the cadelle beetle (*Tenebroides mauritanicus*), and a number of miscellaneous insects, including the yellow mealworm (*Tenebrio molitor*), the Australian spider beetle, and the biscuit beetle. Of the mites that invade mills, storehouses and bakeries, the commonest is the flour mite (*Acarus siro*).

Good housekeeping, with special attention to sacks and bags and their regular cleaning and disinfecting, contributes to insect control. Frequently used insecticides include inert dusts, Pyrethrum (and synergists), gamma BHC. Other contact insecticides or fumigation may be required. The common fumigator is hydrogen cyanide, but methyl bromide and ethylene oxide have been recommended.

In Canada most of the older elevators hold 20,000 to 30,000 bushels (705 to 1,060 cubic metres) of grain, but some hold as much as 100,000 bushels (3,500 cubic metres). A Canadian elevator system at Port Cartier on the St. Lawrence River is designed for the berthing of supertankers; licensed storage capacity of this installation is 10,500,000 bushels (370,000 cubic metres). Unloading of lake vessels can be carried out at 88,000 bushels (3,100 cubic metres) an hour; the two shipping belts each have maximum capacities of 50,000 bushels (1,760 cubic metres) an hour.

In the U.S. storage facilities are similar, though the proportion of wheat exported is not as great as in Canada. Many interior terminals in the U.S. handle large amounts of grain received directly from farmers.

Storage methods in Australia have improved considerably in recent years, with increasing attention given to country storing and the modernization of terminal elevators. There has been a change from bag to bulk handling; 95 percent of the grain was bulk handled by the end of the 1960s. Huge terminal elevators operate in Sydney and Newcastle.

In Argentina large terminal elevators deal with a major export trade, but grading is not as reliable as that in North America. Argentine ports receive the wheat grown in their respective areas, which gives buyers some guidance on grade and type. Considerable quantities of corn (maize) are also exported from Argentina, with precautions taken to ensure reasonably low moisture content to prevent deterioration of cargoes in shipment.

Tilbury Grain Terminal

Handling of grain received in Europe from overseas is a large operation. The Tilbury Grain Terminal in London is a good example of modern grain handling. Capable of servicing bulk carriers of up to 65,000 tons (59,000,000 kilograms), at a maximum rate of 2,000 tons (1,800,000 kilograms) an hour, the terminal feeds adjacent mills and offers a deepwater outlet for transshipment to both rail and road. Two marine leg (dockside) elevators each have a discharge rate of 1,000 tons an hour. Normal silo capacity of 105,000 tons can be extended to 240,000 tons. The silos are 127 feet (38.7 metres) high and individual bin capacities range from 60 to 900 tons. (D.W.K.-J.)

Vegetable farming

The term vegetable in its broadest sense refers to any kind of plant life or plant product; in the narrower sense, as used in this section, however, it refers to the fresh, edible portion of a herbaceous plant consumed in either raw or cooked form. The edible portion may be a root, such as rutabaga, beet, carrot, and sweet potato; a tuber or storage stem, such as potato and taro; the stem, as in asparagus and kohlrabi; a bud, such as brussels sprouts; a bulb, such as onion and garlic; a petiole or leafstalk, such as celery and rhubarb; a leaf, such as cabbage, lettuce, parsley, spinach, and chive; an immature flower, such as cauliflower, broccoli, and artichoke; a seed, such as pea and lima bean; the immature fruit, such as eggplant, cucumber, and sweet corn (maize); or the mature fruit, such as tomato and pepper.

The popular distinction between vegetable and fruit is difficult to uphold. In general, those plants or plant parts that are usually consumed with the main course of a meal are popularly regarded as vegetables, while those mainly used as desserts are considered fruits. This distinction is applied in this section. Thus, cucumber and tomato, botanically fruits, since they are the portion of the plant containing seeds, are commonly regarded as vegetables.

This section will treat the principles and practices of vegetable farming. For a discussion of the food value and the processing of vegetables, see the article FOOD PROCESSING. For a discussion of the cultivation of other plants for human consumption, see below, *Fruit farming*.

TYPES OF PRODUCTION

Vegetable production operations range from small patches of crops, producing a few vegetables for family use or marketing, to the great, highly organized and mechanized farms common in the most technologically advanced countries.

In technologically developed countries the three main types of vegetable farming are based on production of vegetables for the fresh market, for canning, freezing, dehydration, and pickling, and to obtain seeds for planting.

Production for the fresh market. This type of vegetable farming is normally divided into home gardening, market gardening, truck farming, and vegetable forcing.

Home gardening provides vegetables exclusively for family use. About one-fourth of an acre (one-tenth of a hectare) of land is required to supply a family of six. The most suitable vegetables are those producing a large yield per unit of area. Bean, cabbage, carrot, leek, lettuce, onion, parsley, pea, pepper, radish, spinach, and tomato are desirable home garden crops.

Market gardening produces assorted vegetables for a local market. The development of good roads and of motor trucks has rapidly extended available markets; the market gardener, no longer forced to confine his operations to his local market, often is able to specialize in the production of a few, rather than an assortment, of vegetables; a transformation that provides the basis for a distinction between market and truck gardening in the mid-20th century. Truck gardens produce specific vegetables in relatively large quantities for distant markets.

Market gardening

In the method known as forcing, vegetables are produced out of their normal season of outdoor production under forcing structures that admit light and induce favourable environmental conditions for plant growth. Greenhouses, cold frames, and hotbeds are common structures used. Hydroponics, sometimes called soilless culture, allows the grower to practice automatic watering and fertilizing, thus reducing the cost of labour. To successfully compete with other fresh market producers, greenhouse vegetable growers must either produce crops when the outdoor supply is limited or produce quality products commanding premium prices.

Production for processing. Processed vegetables include canned, frozen, dehydrated, and pickled products. The cost of production per unit area of land and per ton is usually less for processing crops than for the same crops grown for market because raw material appearance is not a major quality factor in processing. This difference allows lower land value, less hand labour, and lower handling cost. Although many kinds of vegetables can be processed, there are marked varietal differences within each species in adaptability to a given method.

Specifications for vegetables for canning and freezing usually include small size, high quality, and uniformity. For many kinds of vegetables, a series of varieties having different dates of maturity is required to ensure a constant supply of raw material, thus enabling the factory to operate with an even flow of input over a long period. Acceptable processed vegetables should have a taste, odour, and appearance comparable with the fresh product, retain nutritive values, and have good storage stability. The major vegetables processed commercially are indicated in Table 3.

Vegetables raised for seed production. This type of vegetable farming requires special skills and techniques. The crop is not ready for harvest when the edible portion of

Table 3: Major Vegetables and Kinds of Processing

the plant reaches the stage of maturity; it must be carried through further stages of growth. Production under isolated conditions ensures the purity of seed yield. Special techniques are applied during the stage of flowering and seed development and also in harvesting and threshing the seeds.

PRODUCTION FACTORS AND TECHNIQUES

Consumer demand factors

Profitable vegetable farming requires attention to all production operations, including insect, disease, and weed control and efficient marketing. The kind of vegetable grown is mainly determined by consumer demands, which can be defined in terms of variety, size, tenderness, flavour, freshness, and type of pack. Effective management involves the adoption of techniques resulting in a steady flow of the desired amount of produce over the whole of the natural growing season of the crop. Many vegetables can be grown throughout the year in some climates, although yield per acre for a given kind of vegetable varies according to the growing season and region where the crop is produced.

Climate. Climate involves the temperature, moisture, daylight, and wind conditions of a specific region. Climatic factors strongly affect all stages and processes of plant growth.

Temperature. Temperature requirements are based on the minimum, optimum, and maximum temperatures during both day and night throughout the period of plant growth. Requirements vary according to the type and variety of the specific crop. Based on their optimum temperature ranges, vegetables may be classed as cool-season or warm-season types. Cool-season vegetables thrive in areas where the mean daily temperature does not rise above 70° F (21° C). This group includes the artichoke, beet, broccoli, brussels sprouts, cabbage, carrot, cauliflower, celery, garlic, leek, lettuce, onion, parsley, pea, potato, radish, spinach, and turnip. Warm-season vegetables, requiring mean daily temperature of 70° F or above, are intolerant of frost. These include the bean, cucumber, eggplant, lima bean, okra, muskmelon, pepper, squash, sweet corn (maize), sweet potato, tomato, and watermelon.

Premature seeding, or bolting, is an undesirable condition that is sometimes seen in fields of cabbage, celery, lettuce, onion, and spinach. The condition occurs when the plant goes into the seeding stage before the edible portion reaches a marketable size. Bolting is attributed to either extremely low or high temperature conditions in combination with inherited traits. Specific vegetable strains or varieties may exhibit significant differences in their tendency to bolt.

Young cabbage or onion plants of relatively large size may bolt upon exposure to low temperatures near 50° to 55° F (10° to 13° C). At high temperatures of 70° to 80° F (21° to 27° C) lettuce plants do not form heads and will show premature seeding. The fruit sets of tomatoes are adversely affected by relatively low and relatively high temperatures. Tomato breeders, however, have developed several new varieties, some setting fruits at a temperature as low as 40° F (4° C) and others at a temperature as high as 90° F (32° C).

Moisture. The amount and annual distribution of rainfall in a region, especially during certain periods of development, affects local crops. Irrigation may be required to compensate for insufficient rainfall. For optimum growth and development, plants require soil that supplies water as well as nutrients dissolved in water. Root growth determines the extent of a plant's ability to absorb water and nutrients, and in dry soil root growth is greatly retarded. Extremely wet soil also retards root growth by restricting aeration. Atmospheric humidity, the moisture content of the air, also contributes moisture. Certain seacoast areas characterized by high humidity are considered especially adapted to the production of such crops as the artichoke and lima bean. High humidity, however, also creates conditions favourable for the development of certain plant diseases.

The photoperiod

Daylight. Light is the source of energy for plants. The response of plants to light is dependent upon light intensity, quality, and daily duration, or photoperiod. The seasonal variation in day length affects the growth and flowering of certain vegetable crops. Continuation of vegetative growth, rather than early flower formation, is desirable in such crops as spinach and lettuce. When planted very late in the spring, these crops tend to produce flowers and seeds during the long days of summer before they attain sufficient vegetative growth to produce maximum yields. The minimum photoperiod required for formation of bulbs in garlic and onion plants differs among varieties, and local day length is a determining factor in the selection of varieties.

Each of the climatic factors affects plant growth, and can be a limiting factor in plant development. Unless each factor is of optimum quantity or quality, plants do not achieve maximum growth. In addition to the importance of individual climatic factors, the interrelationship of all environmental factors affects growth.

Certain combinations may exert specific effects. Lettuce usually forms a seedstalk during the long days of summer, but the appearance of flowers may be delayed, or even prevented, by relatively low temperature. An unfavourable temperature combined with unfavourable moisture conditions may cause the dropping of the buds, flowers, and small fruits of the pepper, reducing the crop yield. Desirable areas for muskmelon production are characterized by low humidity combined with high temperature. In the production of seeds of many kinds of vegetables, absence of rain, or relatively light rainfall, and low humidity during ripening, harvesting, and curing of the seeds are very important.

Site. The choice of a site involves such factors as soil and climatic region. In addition, with the continued trend toward specialization and mechanization, relatively large areas are required for commercial production, and adequate water supply and transportation facilities are essential. Topography—that is, the surface of the soil and its relation to other areas—influences efficiency of operation. In modern mechanized farming, large, relatively level fields allow for lower operating costs. Power equipment may be used to modify topography, but the cost of such land renovation may be prohibitive. The amount of slope influences the type of culture possible. Fields with a moderate slope should be contoured, a process that may involve added expense for the building of terraces and diversion ditches. The direction of a slope may influence the maturation time of a crop or may result in drought, winter injury, or wind damage. A level site is generally most desirable, although a slight slope may assist drainage. Exposed sites are not suitable for vegetable farming because of the risk of damage to plants by strong winds.

Soil types

The soil stores mineral nutrients and water used by plants, as well as housing their roots. There are two general kinds of soils—mineral and the organic type called muck or peat. Mineral soils include sandy, loamy, and clayey types. Sandy and loamy soils are usually preferred for vegetable production. Soil reaction and degree of fertility can be determined by chemical analysis. The reaction of the soil determines to a great extent the availability of most plant nutrients. The degree of acid, alkaline, or neutral reaction of a soil is expressed as the pH, with a pH of 7 being neutral, points below 7 being acid, and those above 7 being alkaline. The optimum pH range for plant growth varies from one crop to another. A soil can be made more acid, or less alkaline, by applying an acid-producing chemical fertilizer such as ammonium sulfate.

The inherent fertility of soils affects production quantity, and a sound fertility program is required to maintain productivity. The ability of a soil to support plant life and produce abundant harvests is dependent on the immediately available nutrients in the soil and on the rate of release of additional nutrients that are present but not available to plants. The rate of release of these additional nutrients is affected by such factors as microbial action, soil temperature, soil moisture, and aeration. Depletion of soil fertility may occur as a result of crop removal, erosion, leaching, and volatilization, or evaporation, of nutrients.

Soil preparation and management. Soil preparation for vegetable growing involves many of the usual operations required for other crops. Good drainage is especially important for early vegetables because wet soil retards development. Sands are valuable in growing early vegetables because they are more readily drained than the heavier soils. Soil drainage accomplished by means of ditches or tiles is more desirable than the drainage obtained by planting crops on ridges because the former not only removes the excess water but also allows air to enter the soil. Air is essential to the growth of crop plants and to certain beneficial soil organisms making nutrients available to the plants.

When crops are grown in succession, soil rarely needs to be plowed more than once each year. Plowing incorporates sod, green-manure crops, and crop residues in the soil; destroys weeds and insects; and improves soil texture and aeration. Soils for vegetables should be fairly deep. A depth of six to eight inches (15 to 20 centimetres) is sufficient in most soils.

Soil management involves the exercise of human judgment in the application of available knowledge of crop production, soil conservation, and economics. Management should be directed toward producing the desired crops with a minimum of labour. Control of soil erosion, maintenance of soil organic matter, the adoption of crop rotation, and clean culture are considered important soil-management practices.

Soil erosion

Soil erosion, caused by water and wind, is a problem in many vegetable-growing regions because the topsoil is usually the richest in fertility and organic matter. Soil erosion by water can be controlled by various methods. Terracing divides the land into separate drainage areas, with each area having its own waterway above the terrace. The terrace holds the water on the land, allowing it to soak into the soil and reducing or preventing gullying. In the contouring system, crops are planted in rows at the same level across the field. Cultivation proceeds along the rows rather than up and down the hill. Strip cropping consists of growing crops in narrow strips across a slope, usually on the contour. Soil erosion by wind can be controlled by the use of windbreaks of various kinds, by keeping the soil well supplied with humus, and by growing cover crops to hold the soil when the land is not occupied by other crops.

Maintenance of the organic-matter content of the soil is essential. Organic matter is a source of plant nutrients and is valuable for its effect on certain properties of the soil. Loss of organic matter is the result of the action of micro-organisms that gradually decompose it to carbon dioxide. The addition of manures and the growing of soil-improving crops are efficient means of supplying soil organic matter. Soil-improving crops are grown solely for the purpose of preparing the soil for the growth of succeeding crops. Green-manure crops, grown especially for soil improvement, are turned under while still green and usually are grown during the same season of the year as the vegetable crops. Cover crops, raised for both soil protection and improvement, are only grown during seasons when vegetable crops do not occupy the land. When a soil-improving crop is turned under, the various nutrients that have contributed to the growth of the crop are returned to the soil, adding a quantity of organic matter. Both legumes, those plants such as peas and beans having fruits and seeds formed in pods, and nonlegumes are effective soil-improving crops. The legumes, however, are more valuable, because they contribute nitrogen as well as humus. The rate of decomposition of plant material depends on the kind of crop, its stage of growth, and soil temperature and moisture. The more succulent the material is at the time it is turned under, the more quickly it decomposes. Because dry material decomposes more slowly than green material, it is desirable to turn under soil-improving crops before they are mature, unless considerable time is to elapse between the plowing and the planting of the succeeding crop. Plant material decomposes most rapidly when the soil is warm and well supplied with moisture. If soil is dry when a soil-improving crop is turned under, little or no decomposition will occur until rain or irrigation supplies the necessary moisture.

Crop rotation

The chief benefits derived from crop rotation are the control of disease and insects and the better use of the resources of the soil. Rotation is a systematic arrangement for the growing of different crops in a more or less regular sequence on the same land. It differs from succession cropping in that rotation cropping covers a period of two, three, or more years, while in succession cropping two or more crops are grown on the same land in one year. In many regions vegetable crops are grown in rotation with other farm crops. Most vegetables grown as annual crops fit into a four-or five-year rotation plan. The system of intercropping, or companion cropping, involves the growing of two or more kinds of vegetables on the same land in the same growing season. One of the vegetables must be a small-growing and quick-maturing crop; the other must be larger and late maturing.

In the practice of clean culture, commonly followed in vegetable growing, the soil is kept free of all competing plants through frequent cultivation and the use of protective coverings, or mulches, and weed killers. In a clean vegetable field the possibility of attack by insects and disease-incitant organisms, for which plant weeds serve as hosts, is reduced.

Propagation. Propagation of crop plants, involving the formation and development of new individuals in the establishment of new plantings, is usually accomplished by the use of either seeds or the vegetative parts of plants. The first type, known as sexual propagation, is used for asparagus, bean, broccoli, cabbage, carrot, cauliflower, celery, cucumber, eggplant, leek, lettuce, lima bean, okra, onion, muskmelon, parsley, pea, pepper, pumpkin, radish, spinach, sweet corn (maize), squash, tomato, turnip, and watermelon. The second type, asexual propagation, is used for the artichoke, garlic, girasole, potato, rhubarb, and sweet potato.

Although seed cost is a small portion of the total cost of crop production, seed quality strongly affects crop success or failure. Good seed should be accurately labelled, clean, graded to size, viable, and free of diseases and insects. The reliability of the seed house is an important factor in obtaining good-quality seed. Viability, or ability to grow, and longevity, the period of viability, are characteristics of seeds of any vegetable kind. In cool, dry storage conditions, those vegetable seeds having comparatively short longevity of one to two years are okra, onion, parsley, and sweet corn. Seeds having three-year longevity are those of the asparagus, bean, carrot, leek, and pea; four-year longevity is characteristic of the beet, chard, pepper, pumpkin, and tomato seeds; longevity of five years characterizes the seeds of broccoli, cabbage, cauliflower, celery, cucumber, eggplant, lettuce, muskmelon, radish, spinach, squash, turnip, and watermelon. The dry seeds of all vegetables, when packed under vacuum in hermetically sealed cans, should remain viable for a longer period than seeds stored under less protective conditions.

Viability of seeds

Crops grown from hybrid seeds (the offspring of two or more selected parental varieties and known as F_1) yield vegetables of high quantity and quality. The hybrid-seed industry is based on the production of new seed each year from the controlled pollination of selected parents found to produce the desired combination of characters in the progeny. In the early 1980s the number of F_1 hybrids was increasing in Japan, the United States, and other technically advanced countries. The number of F_1 hybrids varied with the kind of vegetable, but none had yet been introduced for the bean, celery, lettuce, okra, parsley, or pea.

Seedbeds

Planting. Most vegetable crops are planted in the field where they are to grow to maturity. A few kinds are commonly started in a seedbed, established in the greenhouse or in the open, and transplanted as seedlings. Asparagus seeds are planted in a seedbed to produce crowns used for field setting. Some vegetables can be either directly seeded in the field or grown from transplants. These include broccoli, cabbage, cauliflower, celery, eggplant, leek, lettuce, onion, pepper, and tomato. The time and method of planting seeds and plants of a particular vegetable influence the success or failure of the crop. Important factors include the depth of planting, the rate of planting, and the spacing both between rows and between plants within a row.

Factors to be considered in determining the time of planting include soil and weather conditions, kind of crop, and desired harvest time. When more than one planting of a crop is made, the second and later plantings should be timed to provide a continuous harvest for the period desired. The soil temperature required for germination of the planted seed varies markedly with the various kinds of vegetables. Vegetables that will not germinate at a temperature below 60° F (16° C) include the bean, cucumber, eggplant, lima bean, muskmelon, okra, pepper, pumpkin, squash, and watermelon. Temperatures higher than 90° F (32° C) are not favourable for the germination of seeds of celery, lettuce, lima bean, parsley, pea, and spinach.

The quantity of seeds planted, or rate of planting, is mainly determined by the characteristics of the vegetable plant. The size of seeds affects the number of plants raised in a given area. Watermelon varieties, for example, differ in seed size expressed as weight. The Sugar Baby variety has an average weight of 1.4 ounces (41 grams) for 1,000 seeds; those of Blackstone variety average 4.4 ounces (125 grams). If the two are grown on two separate plots of the same area and 4.4 ounces of seeds of each cultivar are planted, the result would be three times as many of the Sugar Baby plants as the Blackstone type. Seed size and plant-growth pattern of a vegetable are major factors that govern the number of plants raised in a given area. The trend in the early 1980s was to increase plant population for many crops to achieve the greatest yield possible without impairing quality. As plant population increases per unit area, a point is reached at which each plant begins to compete for certain essential growth factors—*e.g.*, nutrients, moisture, and light. When the population is below the level in which competition between plants occurs, increased population will have no effect on individual plant performance, and the yield per unit area will increase in direct proportion to the increment of population. When competition for essential growth factors occurs, however, yield per plant decreases.

Transplants

Early harvest and economical use of space are the principal objectives of growing vegetable crops from transplants produced in a greenhouse or outdoor seedbed. It is easier to care for young plants of the cabbage, cauliflower, celery, onion, and tomato in small seedbeds than to sow the seeds in the place where the crop is to grow and mature. Land is free longer for another crop, and weeds, insects, diseases, and irrigation are more readily and economically controlled. The production of transplants is often a specialty of growers who sell their produce to other vegetable growers. The seeds may be planted at a rate three to six times that commonly used for a direct-seeded field. The young plants are removed for use as transplants when they reach the desired size and age, approximately 40 to 60 days after seeding.

Care of crops during growth. Practices required for a vegetable crop growing in the field include cultivation; irrigation; application of fertilizers; control of weeds, diseases, and insects; protection against frost; and the application of growth regulators if necessary.

Cultivation. Cultivation refers to stirring the soil between rows of vegetable plants. Because weed control is the most important function of cultivation, this work should be performed at the most favourable time for weed killing, when the weeds are breaking through the soil surface. When the plants are grown on ridges, it is necessary to cover the basal plant portion with soil in the case of such vegetables as asparagus, carrot, garlic, leek, onion, potato, sweet corn, and sweet potato.

Irrigation. Vegetable production requires irrigation in arid and semi-arid regions, and irrigation is frequently used as insurance against drought in more humid regions. In areas having intermittent rain for five or six months, with little or none during the remainder of the year, irrigation is essential throughout the dry season and may also be needed between rainfalls in the rainy season. The two types of land irrigation generally suited to vegetables are surface irrigation and sprinkler irrigation. A level site is required for surface irrigation, in which the water is conveyed directly over the field in open ditches at a slow, nonerosive velocity. Where water is scarce, pipelines may be used, eliminating losses caused by seepage and evaporation. The distribution of water is accomplished by various control structures, and the furrow method of surface irrigation is frequently employed because most vegetable crops are grown in rows. Sprinkler irrigation conveys water through pipes for distribution under pressure as simulated rain.

Irrigation requirements

Irrigation requirements are determined by both soil and plant factors. Soil factors include texture, structure, water-holding capacity, fertility, salinity, aeration, drainage, and temperature. Plant factors include type of vegetable, density and depth of the root system, stage of growth, drought tolerance, and plant population (see above *Irrigation and drainage*).

Fertilizer application. Soil fertility is the capacity of the soil to supply the nutrients necessary for good crop production, and fertilizing is the addition of nutrients to the soil. Chemical fertilizers may be used to supply the needed nitrogen, phosphorus, and potassium. Chemical tests of soil, plant, or both are used to determine fertilizer needs, and the rate of application is usually based on the fertility of the soil, the cropping system employed, the kind of vegetable to be grown, and the financial return that might be expected from the crop. Methods of fertilizer application include scattering and mixing with the soil before planting; application with a drill below the surface of the soil at the time of planting; row application before or at planting time; and row application during plant growth, also called side-dressing. Plowed down broadcast fertilizers have recently been used in combination with high analysis liquid fertilizers applied at planting or as a side-dressed band. Mechanical planting devices may employ fertilizer attachments to plant the fertilizer in the form of bands near the seed. For most vegetables, the bands are placed from two to three inches (five to 7.5 centimetres) from the seed, either at the same depth or slightly below the seed.

Use of herbicides

Weed control. Weeds (plants growing where they are not wanted) reduce crop yield, increase production cost, and may harbour insects and diseases that attack crop plants. Methods employed to control weeds include hand weeding, mechanical cultivation, application of chemicals acting as herbicides, and a combination of mechanical and chemical means. Herbicides, selective chemical weed killers, are absorbed by the plant and induce a toxic reaction. The amount and type of herbicide that can be safely used to protect vegetable crops depends on the tolerance of the specific crops to the chemical. Most herbicides are applied as a spray, and the appropriate time for application is determined by the composition of the herbicide and the kind of vegetable crop to be treated. Preplanting treatments are applied before the crop is planted; preemergence treatments are applied after the crop is planted but before its seedlings emerge from the soil; and postemergence treatments are applied to the growing crop at a definite stage of growth.

Disease and insect control. The production of satisfactory crops requires rigorous disease- and insect-control measures. Crop yield may be lowered by disease or insect attack, and when plants are attacked at an early stage of growth the entire crop may be lost. Reduction in the quality of vegetable crops may also be caused by diseases and insects. Grades and standards for market vegetables usually specify strict limits on the amount of disease and insect injury that may be present on vegetables in a designated grade. Vegetables remain vulnerable to insect and disease damage after harvesting, during the marketing and handling processes. When a particular plant pest is identified, the grower can select and apply appropriate control measures. Application of insect control at the times specific insects usually appear or when the first insects are noticed is usually most effective. Effective disease control usually requires preventive procedures.

Control of plant diseases

Diseases are incited by such living organisms as bacteria, fungi, and viruses. Harmful material enters the plant, develops during an incubation period, and finally causes infection, the reaction of the plant to the pathogen, or disease-producing organism. Control is possible during the inoculation and incubation phases, but when the plant reaches the infection stage it is already damaged. Typical plant diseases include mildew, leaf spots, rust, and wilt. Chemical fungicides may be used to control disease, but the use of disease-resistant plant varieties is the most effective means of control.

Vegetable breeders have developed plant varieties resistant to one or more diseases; such varieties are available for the bean, cabbage, cucumber, lettuce, muskmelon, onion, pea, pepper, potato, spinach, tomato, and watermelon.

Insects are usually controlled by the use of chemical insecticides that kill through toxic action. Many insecticides are toxic to harmful insects but do not affect bees, which are valuable for their role in pollination.

Frost protection. Frost protection may be accomplished by increasing the amount of heat radiated from the soil when frost is likely to occur. Irrigation on the day before a predicted frost provides additional moisture in the soil to increase the amount of heat given off as infrared rays. This extra heat protects thc plants from frost injury. A continuous supply of water provided by sprinkler irrigation may also protect plants from frost. As the water freezes on the plant leaves, it loses heat that is absorbed by the plant leaves, maintaining leaf temperature at 32° F (0° C). Because of the sugars and other substances in plant cells, the freezing point of cell sap is somewhat lower than 32° F.

Growth regulators. It is somctimes desirable to retard or accelerate maturity in vegetable crops. A chemical compound may be applied to prevent sprouting in onion crops. It is applied in the field sufficiently early for absorption by the still-green foliage but late enough to avoid suppressing the bulb yield. Another substance may be used to end the dormancy, or rest period, of newly harvested potato tubers intended for planting. The treated seed potatoes have uniform sprout emergence. The same substance is applied to celery from two to three weeks before harvest to elongate the stalks and increase the yield and is also used to accelerate maturity in artichokes. A chemical compound, applied when adverse weather conditions prevail during the period of fruit setting, has been used to encourage fruit set.

Harvesting. The stage of development of vegetables when harvested affects the quality of the product reaching the consumer. In some vegetables, such as the bean and pea, optimum quality is reached well in advance of full maturity and then deteriorates, although yield continues to increase. Factors determining the harvest date include the genetic constitution of the vegetable variety, the planting date, and environmental conditions during the growing season. Successive harvest dates may be obtained either by planting varieties having different maturity dates or by changing the sequence of planting dates of one particular variety. The successive method is applicable to such crops as broccoli, cabbage, cauliflower, muskmelon, onion, pea, sweet corn (maize), tomato, and watermelon. Certain varieties of the carrot, celery, cucumber, lettuce, parsley, radish, spinach, or summer squash can be sown in succession throughout most of the year in some climates, thus prolonging the harvest period. The length of time required for various vegetables to reach the harvest stage and the age of their fruit at that point is shown in Table 4.

Successive harvest dates

Hand harvesting is employed along with various mechanical aids for broccoli, cabbage, cauliflower, muskmelon, and pepper crops. Many vegetables grown for proccssing and some vegetables destined for the fresh market are mechanically harvested. Harvesting operations may be performed by a single machine in a single step for such vegetable crops as the bean, beet, carrot, lima bean, onion, pea, potato, radish, spinach, sweet corn, sweet potato, and tomato. Designers of harvesting machinery have been working to develop a multiple-picking harvester capable of adjustment for use with more than one crop. Vegetable breeders have been able to produce vegetables with characteristics suitable for machine harvesting, including compact plant growth, uniform development, and concentrated maturity.

Table 4: Market Maturity of Vegetables

	number of days from planting to markct maturity	age of fruit, in days, at market maturity
Bean	50–60	7–10
Beet	60–70	—
Broccoli*	50–80	—
Brussels sprouts*	90–100	—
Cabbage*	70–100	—
Carrot	70–80	—
Cauliflower*	60–120	—
Celery*	90–120	—
Chard	50–60	—
Chicory*	60–70	—
Cucumber	50–70	5–20

Sweet potato	120–150	—
Tomato*	70–90	45–60
Turnip	45–60	—
Watermelon	85–100	40–50

*From time of transplanting.

STORAGE

Post-harvest changes

Fresh vegetables are living organisms, and there is a continuation of life processes in the vegetable after harvest. Changes that occur in the harvested, nonprocessed vegetable include water loss, conversion of starches to sugars, conversion of sugars to starches, flavour changes, colour changes, toughening, vitamin gain or loss, sprouting, rooting, softening, and decay.

Some changes result in quality deterioration; others improve quality in those vegetables that complete ripening after harvest. Postharvest changes are influenced by such factors as kind of crop, air temperature and circulation, oxygen and carbon dioxide contents and relative humidity of the atmosphere, and disease-incitant organisms. To maintain the fresh vegetable in the living state, it is usually necessary to slow the life processes, though avoiding death of the tissues, which produces gross deterioration and drastic differences in flavour, texture, and appearance.

Storage of vegetables contributes to price stabilization by carrying over produce from periods of high production to periods of low production. It also extends the period of consumption of many kinds of vegetables. Storage conditions can contribute to the preservation of the natural living state of the edible portion and to the prevention of deterioration through control of temperature, relative humidity, and the quality of the produce to be stored. Vegetables for storage must be free from mechanical, insect, and disease injury and should be at the proper stage of maturity.

Common (unrefrigerated) storage and cold (refrigerated) storage are the methods generally employed for vegetables. Common storage, lacking precise control of temperature and humidity, includes the use of insulated storage houses, outdoor cellars, or mounds. Cold storage allows precise regulation of temperature and humidity and maintenance of constant conditions by use of a refrigeration and ventilation system. Recommended storage conditions and duration for a number of different vegetables are given in Table 5. Temporary storage, suitable only for very brief storage periods, is frequently practiced in the shipping season when large lots are accumulated for carload or truck quantities. The refrigerator car or truck is a means of temporary storage used to protect produce while it is in transit. Short-term storage may last for four or six weeks. Economic factors, such as the probability that prices will increase later in the season, encourage long-term storage of such perishable vegetables as the onion, potato, and sweet potato (see Table 5).

Table 5: Recommended Storage Conditions of Vegetables

	temperature (°F)	relative humidity (percent)	approximate length of storage (days)
Asparagus	32	90–95	21–28
Bean, snap	45	85–90	8–10
Beet, topped	32	90–95	30–90
Beet, not topped	32	90–95	10–14
Broccoli	32	90–95	7–10
Brussels sprouts	32	90–95	21–28
Cabbage	32	90–95	90–120
Carrot, topped	32	90–95	120–150
Carrot, not topped	32	90–95	10–14
Casaba melon	40–50	80–85	10–42
Cauliflower	32	90–95	14–21
Celery	31–32	90–95	60–120
Cucumber	45–50	90–95	10–14
Eggplant	45–50	90–95	10
Garlic	32	70–75	180–240
Leek	32	85–90	30–90
Lettuce	32	90–95	14–21
Lima bean, shelled	32	90–95	15
Lima bean, unshelled	32	90–95	14–28
Okra	50	85–95	14
Onion	32	70–75	180–240
Pea	32	85–90	7–14
Pepper	45	85–90	8–10
Potato	38–40	85–90	180–270
Pumpkin	50–55	70–75	60–180
Spinach	32	90–95	10–14
Squash, summer	40–50	85–95	14–21
Sweet corn	31–32	90–95	4–8
Sweet potato	55–60	80–95	120–180
Tomato, ripe	40–50	85–90	7–10
Tomato, mature green	55–70	80–85	21–35
Turnip, topped	32	90–95	120–150
Watermelon	36–40	80–85	7–14

PREMARKETING OPERATIONS AND SELLING

Premarketing operations include washing, trimming, waxing, precooling, grading, prepackaging, and packaging. Vegetables often require washing after harvest to remove any adhering soil particles. Such vegetables as the beet, carrot, celery, lettuce, radish, spinach, and turnip are trimmed before washing to remove discoloured leaves or to cut back the green tops. Waxing of the cucumber, muskmelon, pepper, potato, sweet potato, and tomato gives the product a bright appearance and controls shrivelling through reduction of moisture loss.

Waxing

Precooling. Precooling, the rapid removal of heat from freshly harvested vegetables, allows the grower to harvest produce at optimum maturity with greater assurance that it will reach the consumer at maximum quality. Precooling benefits the vegetable by slowing the natural deterioration that starts shortly after harvest, slowing the growth of decay organisms and reducing wilt by retarding water loss. The major precooling methods include hydrocooling, contact icing, vacuum cooling, and air cooling. In hydrocooling the vegetable is cooled by direct contact with cold water flowing through the packed containers and absorbing heat directly from the produce. In contact icing crushed ice is placed in the package or spread over a stack of packages to precool the contents. The vacuum cooling process produces rapid evaporation of a small quantity of water, lowering the temperature of the crop to the desired level. Air cooling involves the exposure of vegetables to cold air; the air must be as cold as possible for rapid cooling but not low enough to freeze the produce exposed to the direct air blast.

The preferred method of precooling varies according to the physical characteristics of the vegetable. Hydrocooling is recommended for the asparagus, beet, broccoli, carrot, cauliflower, celery, muskmelon, pea, radish, summer squash, and sweet corn (maize); cabbage, lettuce, and spinach are suited to vacuum cooling; air cooling is preferred for bean, cucumber, eggplant, pepper, and tomato. After the produce is precooled, it is desirable to maintain low temperature by shipping in refrigerator cars or trucks, by storing in cold-storage rooms, and by refrigeration in retail stores.

Grading. Uniformity in size, shape, colour, and ripeness is of great importance in marketing any vegetable product, and can be secured through grading. The establishment of standard grades furnishes a basis of trade. Grade standards are based mainly on general appearance, size, trueness to type, and freedom from blemishes and defects.

Packaging. Prepackaging, or consumer packaging, has become a highly organized practice, often employing elaborate equipment. The product is placed in bags made of transparent film, trays or cartons overwrapped with transparent film, or mesh or paper bags. The packaging of produce in consumer packages lends itself to self-service in retail stores. The production region is often the most satisfactory location for prepackaging, especially when a packaging centre serves a large vegetable-growing area.

Master containers for consumer packages are commonly made of paperboard. Cartons, bags, baskets, boxes, crates, and hampers of various kinds and sizes are all used in packaging vegetables for marketing. The type of container is selected to fit the kind of vegetable; it furnishes a convenient means for transport, loading, and stacking, with security and economy of space. Uniform product throughout the package is an important consideration in packing vegetables.

Selling. Producers sell vegetables through various retail and wholesale practices. Retail sales are made directly to the consumer, often through roadside stands. Many growers sell most of their produce at wholesale to retail stores, to various types of buyers on local markets in nearby cities, or in regional markets. Growers located long distances from markets sell largely to wholesale dealers or jobbers.

Retail sales

Some growers have contracts with processors. Wholesale marketing arrangements are also made through auction markets in the producing regions and through cooperative organizations of producers. (W.A.W.)

Fruit farming

The subject of fruit and nut production deals with intensive culture of perennial plants, the fruits of which have economic significance (a nut is a fruit, botanically). It is one part of the broad subject of horticulture, which also encompasses vegetable growing and production of ornamentals and flowers. This section places further arbitrary limitations in that it does not encompass a number of very important perennial fruit crops covered elsewhere, including vanilla, coffee, and the oil-producing tung tree and oil palm (see FOOD PROCESSING; BEVERAGE PRODUCTION).

Botanists define a fruit in broad terms as the fleshy or dry ripened ovary surrounding the seed of a plant. A pomologist, or specialist in the science and practice of fruit growing, defines it somewhat more narrowly as the fleshy edible part of a perennial plant associated with development of the flower. A nut is any seed or fruit consisting of a kernel, usually oily, surrounded by a hard or brittle shell. Most edible nuts—*e.g.,* almond, walnut, cashew, pecan, pistachio, etc.—are well known as dessert nuts. Not all nuts are edible. Some, used as sources of oil or fat, may be regarded as oil seeds; others are used for ornament. The botanical definition of a nut, based on features of form and structure (morphology), is more restrictive: a hard, dry, one-celled, one-seeded fruit that does not split open at maturity. Among the nuts that fit both the botanical and popular conception are the acorn, chestnut, and filbert; other so-called nuts may be botanically a seed (Brazil nut), a legume (peanut [groundnut]), or a drupe (almond

Table 6: Scientific Names, Probable Original Source, and Uses of Fruits and Nuts

common name	scientific name of main crop	probable original source	principal uses*
Fruits			
Apple	*Malus pumila*	southeastern Europe, southwestern Asia	food, firewood
Apricot	*Prunus armeniaca*	China	food
Avocado (alligator pear)	*Persea americana*	Mexico to Colombia	food
Banana	*Musa sapientum* (common) *M. cavendishii* (dwarf) *M. paradisiaca* (plantain)	Asia (southeastern)	food
Blackberry	*Rubus allegheniensis*		food
Blueberry	*Vaccinium corymbosum*	North America	food
Cherry	*Prunus cerasus* (tart); *P. avium* (sweet)	western Asia and eastern Europe	food, wood
Citrus			
Orange	*Citrus sinensis*	Malay archipelago	food
Grapefruit	*C. paradisi*	Jamaica (?)	food
Lemon	*C. limon*	E. Indian archipelago	food, oil
Lime	*C. aurantifolia*	E. Indian archipelago	food, oil
Cranberry	*Vaccinium macrocarpon*	North America	food
Currant	*Ribes sativum* (red) *R. nigrum* (black)	western Europe	food
Date	*Phoenix dactylifera*	southern Iraq	food
Fig	*Ficus carica*	Mediterranean area	food
Gooseberry	*Ribes hirtellum* (American) *R. uva-crispa* (European)	North Africa, western Europe	food
Grape	*Vitis vinifera* (European) *V. labrusca* (American)	Caspian Sea area Atlantic slope, North America	food
Guava†	*Psidium guajava* (common) *P. cattleianum* (strawberry)	tropical America	food
Mango	*Mangifera indica*	East India, Burma, Assam, Malaya	food
Mangosteen†	*Garcinia mangostana*	Southeast Asia	food
Olive	*Olea europaea*	E. Mediterranean area	food, oil
Peach	*Prunus persica*	China	
Papaya	*Carica papaya*	Central America, Mexico	food, papain (meat tenderizer)
Passion fruit	*Passiflora edulis*	tropical America	food flavouring
Pineapple	*Ananas comosus*	West Indies	food
Plum	*Prunus domestica*	Caucasus area	food
Raspberry	*Rubus idaeus* (red) *R. occidentalis* (black) *R. neglectus* (purple)	eastern Asia	food
Strawberry	*Fragaria* sp. (8)	Americas	food
Nuts			
Almond (sweet)	*Prunus amygdalus*	W. temperate India and Persia	food
Almond (bitter)	*P. amygdalus,* var. *amara*	W. temperate India and Persia	flavouring extract
Almondette	*Buchanania lanzan*	India, Burma	food
Araucarian pine nut (piñon, pinyonie)	*Araucaria araucana*	Chile	food
Arnut (yer-nut, earth chestnut, hawk nut, lousy-nut)	*Bunium* species	W. Europe to Caucasus	food
Australian nut, *see* Macadamia			
Babassu nut	*Orbignya oleifera*	Brazil	food, fuel oil
Bambarra groundnut	*Voandzeia subterranea*	tropical Africa	food
Barbados nut (physic nut)	*Jatropha curcas*	tropical America	medicine
Baroba	*Diplodiscus paniculatus*	Philippines	starchy seeds boiled and eaten
Beech nut, American	*Fagus grandifolia*	E. United States	
Beech nut, European	*Fagus sylvatica*	Cent. Europe, S.W. Asia	salad oil
Ben nut	*Moringa oleifera*	India, West Indies	artists' oil, lubricant
Betel nut (areca nut, pinang)	*Areca catechu*	E. tropics	masticatory
Bladdernut	*Staphylea* species	temperate North America, S. Europe, S. Asia	necklaces
Bomah nut	*Pycnocoma macrophylla*	Africa	tanning, poison
Bonduc nut	*Caesalpinia bonduc*	Tropics	medicine, beads
Brazil nut (castanea, creamnut, para nut)	*Bertholletia excelsa*	Amazon basin, Brazil	food
Breadfruit, African	*Treculia africana*	tropical Africa	seeds ground for meal
Bread nut	*Brosimum alicastrum*	tropical America	food
Butternut (long or white walnut)	*Juglans cinerea*	E. United States, S.E. Canada	food
Butter pit, *see* Naras nut			
Candlenut	*Aleurites moluccana*	Malaysia	drying
Cashew (acajou, caja, cajou)	*Anacardium occidentale*	West Indies, Brazil	food, oil, wood, varnish, paint
Castanopsis nut (golden chinquapin, wild chestnut)	*Castanopsis* species	S.E. Asia, California	food
Chestnut	*Castanea* species	E. United States, S. Europe, N. Africa, Asia	food
Chile hazel	*Gevuina avellana*	Chile	food
Chinquapin	*Castanea* species	S.E. United States, China	food
Chufa (rush nut, earthnut, ground almond)	*Cyperus esculentus*	S. Europe	food
Cobnut, *see* Filbert			
Cobnut, Jamaican	*Omphalea diandra*	West Indies, tropical America	food, oil
Coconut	*Cocos nucifera*	Old World tropics	food, oil

Nicari Palm nut	*Cocos coronata*	Brazil	food
Nitta nut (nete)	*Parkia biglobosa*	tropical Africa	food
Nutmeg	*Myristica fragrans*	East Indies	spice
Olive	*Elaeocarpus ganitrus*	India	beads, ornaments
Owusa nut	*Plukenetia conophora*	W. tropical Africa	food
Oyster nut	*Telfairia pedata*	E. Africa	food
Palm chestnut	*Guilielma gasipaes*	tropical South America	food
Palm nut	*Elaeis guineensis*	W. Africa	oil
Paradise nut (sapucaia nut)	*Lecythis zabucajo*	Brazil	food
Pascualito nut (pinonchillo)	*Garcia nutans*	Mexico to Venezuela	quick-drying oil
Peanut (groundnut)	*Arachis hypogaea*	Brazil	food
Peanut, hog	*Amphicarpa monoica*	North America	food
Pecan (Illinois nut)	*Carya illinoensis*	S. United States	food
Pili nut	*Canarium ovatum*	Pacific tropics	food
Pine nut (piñon, pignolia)	*Pinus* species	S.W. United States, Europe, Asia	food
Pistachio (pistache, green almond)	*Pistacia vera*	Mediterranean basin to Iran, S.W. Asia	food
Poison nut	*Strychnos nuxvomica*	India	medicine
Quandong nut	*Fusanus acuminatus*	Australia	food
Ravensara nut (clove nutmeg)	*Ravensara aromatica*	Madagascar	spice
Rose nut (red nut)	*Hicksbeachia pinnatifolia*	Australia	ornamental, food
Sassafras nut	*Ocotea* species	South America	aromatic
Shea butter nut	*Butyrospermum parkii*	tropical Africa	food, soap oil
Singhara nut (water nut)	*Trapa bispinosa*	India, Kashmir	food
Snake nut	*Ophiocaryon paradoxum*	Guiana	charm for snakebite
Soap nut	*Sapindus saponaria*	S. Florida to N. South America	soap substitute
Soap nut, Indian	*Sapindus inocarpus*	India	soap substitute
Sterculia nut	*Sterculia foetida*	tropical Africa	food
Swarri nut (souari nut, sawarri nut, pekea nut, butter nut, piki)	*Caryocar* species	tropical America	food
Tacey nut	*Caryodendron orinocense*	Colombia	food
Taqua nut (ivory nut, vegetable ivory)	*Phytelephas macrocarpa*	Central America	ornaments, buttons
Tahiti chestnut (South Sea chestnut)	*Inocarpus edulis*	South Seas	food
Tallow nut (false sandalwood)	*Ximenia americana*	tropical Africa	food
Tallow nut, Chinese	*Sapium sebiferum*	China	wax for soap and candles
Tiger nut, *see* Chufa			
Tonka bean (tonqua or tonquin bean, coumara nut)	*Dipteryx odorata*	tropical South America	perfume
Torreya nut (kaya nut)	*Torreya nucifera*	China, Japan	food, oil
Tropical almond (myrobalan, Indian almond)	*Terminalia catappa*	S.W. Asia	food
Tung nut (wood-oil tree)	*Aleurites* species	S. China	paint, varnish, oil
Walnut, African	*Coula edulis*	W. tropical Africa, Congo	food
Walnut, Persian	*Juglans regia*	Orient	food, wood
Walnut, Black	*J. nigra*	North America	food, wood, ground shells for blasting, polishing, etc.
Water chestnut (water caltrop)	*Trapa natans*	Europe, Asia	food
Water chestnut, Chinese (matai)	*Eleocharis tuberosa*	S. China	food
Yeheb nut	*Cordeauxia edulis*	Somalia	food

*All fruits listed are eaten fresh. Most fruits can be canned, although some freeze better, such as blueberry, strawberry, raspberry, cranberry, and peach. Jellies, jams, juices, cider, and spirits are products of most fruits, although some are better adapted than others, such as apple and peach. Some fruits are adapted to drying, particularly those relatively high in sugar, such as prune, some peaches, fig, and some grapes. †Noncommercial.

and coconut). In this section the term nut is used in its broadest sense unless otherwise indicated.

This section treats the principles and practices of fruit cultivation. For a discussion of the processing of fruits, see the article FOOD PROCESSING; for information on their nutritive value, see NUTRITION.

Improvements in technology and consolidation of the fruit and nut industries in the most favoured climates of the world have been responsible for a steady increase in yield. Thus, the total acreage or number of plants devoted to various fruit and nut crops has dropped, remained about the same, or not risen in proportion to the increase in the respective crop production.

Although fruit- and nut-growing enterprises cover great ranges of climates and plant materials, their technologies have many common problems and practices. The most significant of these are discussed below.

THE VARIETY: ITS PROPAGATION AND IMPROVEMENT

Selection of plants

The first step in establishing a fruit- or nut-growing industry is the selection of individual plants with high productivity and a superior product. Such an individual is a horticultural variety. If it is multiplied vegetatively from rooted cuttings, from root pieces that throw shoots, or by graftage, each plant in the group (called a clone) that results is identical with the others. Nearly all commercially important perennial fruit and nut crops are clonally propagated; *i.e.,* their varieties are multiplied vegetatively by one means or another. Some nut crops, such as the wild pecan, cashew, black walnut, hickory, and chestnut still come from trees that grow at random from seed; hence, character and quality tend to vary.

Many important varieties of fruit plants were selected generations ago. The Sultanina (Thompson Seedless) grape, the Lob Injir (Calimyrna) fig, and the Gros Michel banana have obscure origins; planted by the millions since selection, each specimen is actually a vegetative continuation of the selected individual growing on an independent root system. But regardless of the age of a fruit-growing industry, or the perfection of some of the selected varieties, a continuing search for new varieties is essential. There is always room for improvement in climatic adaptability, in insect and disease resistance, and in the solution of special horticultural or marketing problems. In fact, government experiment stations over the world now stress scientific breeding for improvement of market quality and yield of key fruit and nut crops.

Not only are varietal selection and improvement a continuing need but so also is the maintenance of existing varieties. Although an improved vegetative mutation of a variety is exceptional, the opportunities for accidental multiplication of degenerate (low-quality) mutants increase in proportion to the number of specimens of the variety. As a result, care is taken to propagate a clone only from superior individuals, and in the case of citrus, where mutation is especially common, further precautions are necessary. There are, of course, occasional mutations that may greatly improve a variety and these are sought, selected, and propagated.

Vegetative propagation technique

Vegetative propagation technique varies with the individual fruit plant. Date, banana, and pineapple are multiplied by use of offshoots or suckers. Grape, fig, olive, currant, and blueberry are usually propagated from cuttings. Strawberry and black raspberry reproduce vegetatively by special organs—the former by stolons or runners, the latter by cane tip rooting or layering. Many kinds of fruit trees must be grafted or budded on especially grown rootstocks because the species to be multiplied does not root itself easily; apple, pear, peach, mango, and citrus are examples of this group. Many nut trees have a single taproot with but few branching roots, necessitating a deep hole and special care in transplanting.

Today's trend is toward a smaller tree in most fruit crops, particularly the apple and pear, and toward closer planting in hedgerow style, with carefully regulated fertilization and irrigation (Figure 11). This increases production per acre, lowers labour cost, increases early yields, and facilitates access in maintenance and harvesting. This approach, in fact, has been used for decades in Europe. Labour is the largest element of cost in fruit and nut production. Every means is exploited to reduce, facilitate, or eliminate hand labour.

With most fruit species a period of one to two years intervenes between the time a cutting is rooted and the time the plant is ready for setting in the field, or between graftage or budding and field planting. During this interval the plants remain in a nursery where they can be given intensive culture in rows. Pineapple and banana planting materials, however, do not require nursery care before field planting.

In choosing fruit varieties, the grower must (1) recognize the relative adaptabilities of available varieties to the climatic and soil conditions of his farm and (2) select a group that satisfies both his management needs and the market

(Bottom right) Apple trees grown on dwarf stocks to produce higher yields per ground unit.

demands from those best adapted to his conditions. For instance, an apple producer in the northeastern U.S. may raise four varieties: Milton, McIntosh Red, Red Delicious, and Rome Beauty. The main harvest seasons for these succeed each other at two-week intervals; this helps him extend the harvest period and make efficient use of his labour. The first two varieties cross-fertilize satisfactorily, as do the last two. The first of these varieties is usually marketed without storage, while the storage seasons of the others are of increasing length. This helps the grower to extend his marketing period.

CULTIVATION

Site selection. The site of a fruit-growing enterprise is as significant in determining its success as the varieties grown. In fact, variety and site together set a ceiling on the productivity and profit that can be realized under the best management. In most developed fruit regions microclimatic conditions (climate at plant height, as influenced by slight differences in soil, soil covering, and elevation) and soil conditions are the two components of a site that determine its desirability for a fruit-growing enterprise. Sometimes (particularly with highly perishable fruits) transportation to market must also be considered.

Climate, soil conditions

Local conditions at a site that expose it to unusual frost hazard are as detrimental to citrus in Florida as they are to peach trees in New Zealand and apple trees in the south of England. In regions and sites where temperatures during the season may drop no more than a few degrees below freezing, artificial frost protection is sometimes used. This is accomplished by open-flame burning (petroleum bricks, logs, etc.) or heating of metal objects with oil, gas, propane, electricity, etc. (stones or stacks that radiate heat). Another technique is the spraying of water on plants (*e.g.*, strawberries) as long as the temperature is below freezing.

For highest productivity, most fruit trees must root extensively to a depth of three feet (one metre) or more. Heavy subsoil or other conditions causing imperfect internal drainage may result in shallow, weak root systems that do not take water and nutrients efficiently from the soil. In semi-arid and arid regions, accumulation of saline soils in a subsurface layer sometimes limits rooting of fruit trees, causes abnormal foliar symptoms, and reduces yields. Tiling and surface ditching help decrease water accumulation in poorly drained subsoils and reduce wet spots in otherwise satisfactory sites. Special control of irrigation procedures and periodic leaching may alleviate the worst salt effects in saline soils. Choice of tolerant species, varieties, and rootstocks may make fruit growing economical on imperfectly drained or mildly saline sites, though plants rarely perform as well as they do on sites free from these difficulties. Coconuts, however, tolerate saline soil conditions near tropical saltwater coasts.

Once selected, a site is cleared, levelled (if needed), and cultivated. Then drainage, irrigation, and road systems are installed as required. In rolling or sloping terrain, where contour planting is needed to control erosion and conserve moisture, the locations of the plant or row positions are determined by the contour terraces and waterways established. In old lands, nematode or other pest populations make fumigation necessary before planting. In some problem California soils, giant plows and treaded tractors turn the soil to depths of three to six feet (one to two metres). In very infertile sites, or sites where the physical condition of the surface soil is poor, it may be helpful to grow a succession of leguminous cover crops for a year or more before planting and/or apply a fertilizer containing major fertilizer elements (nitrogen, potassium, phosphorus, calcium, sulfur) and all or certain trace elements (iron, manganese, boron, zinc, copper, molybdenum) and lime, based on a soil test.

Planting and spacing systems. Growth, flowering habits, and light requirements on the one hand, and management problems on the other, determine the most satisfactory planting plan for a fruit- and nut-growing enterprise. There is a trend toward use of dwarfing stocks, growth control chemicals, or closer planting and training, or all of them to get the highest yields and best operation efficiency possible on a unit of ground.

Low-growing crops such as strawberry and pineapple are usually managed in beds containing several rows, or in less formal matted rows. In an acre of strawberries, 200,000 or more plants may occupy the matted rows. A pineapple plantation with two-row beds, having plants one foot (0.3 metre) apart in rows two feet (0.6 metre) apart totals 15,000 to 18,000 plants per acre (37,000 to 44,000 per hectare). With such dense populations, intense competition for light, water, and nutrients causes smaller average fruit size. Nevertheless, the total yield per unit of land is usually greater than it would be with lower plant numbers.

The spacing of grapevines along a trellis row and of trees planted in hedgerows involves the same group of problems. Maximum vineyard production frequently results with vine distances of eight to nine feet (2.4 to 2.7 metres; 600 ± per acre [1,500 per hectare]). The trend for peach trees and spur-type apple strains is hedgerows 14 feet (4.2 metres) apart or closer, in rows 18 to 20 feet (5.4 to 6 metres) apart.

With those species and varieties that require cross-pollination by insects, the planting plan must take those special needs into account. This is a problem with apple, pear, plum, and sweet cherry orchards. At least two varieties that cross-fertilize successfully must be planted in association with each other.

Training and pruning. Pruning is the removal of parts of a plant to influence growth and fruitfulness. It is an important fruit-growing practice. Primary attention is given to form in the first few years after fruit trees or vines are planted. Form influences strength and longevity of the mature plant as well as efficiency of other fruit-growing practices; pruning for form is called training. As the plant approaches maximum fruitfulness and fills its allotted space, maintenance pruning for various purposes becomes increasingly important.

The grape may be trained following one of two systems: (1) spur system, cutting growth of the previous season (canes) to short spurs, (2) long-cane system, permitting canes to remain relatively long. Whether a spur or long-cane system is followed depends on the flowering habit of the variety. Relatively small trees that respond favourably to severe annual pruning (*e.g.*, the peach and Kadota fig) are usually trained to create an open-centred tree with a scaffold of four or five main branches that originate on a short trunk and branch a number of times to provide fruiting wood. Annual renewal pruning can be reasonably efficient under these circumstances. Larger trees that do not respond favourably to heavy annual pruning are trained best to a system that encourages the main leader branch to grow erect to a height of eight to 10 feet (2.4–3.0 metres), with four or five main lateral branches at intervals on its sides forming the scaffold that carries fruiting wood up and out; this is called a modified leader system. The central leader type of tree, with one main leader up through the centre and many side branches, is common for pear and apple planted in hedgerows, and possibly for other fruits and nuts as the close-planted hedgerow system is more widely adopted.

Maintenance pruning

The principal reasons for maintenance pruning are: (1) to permit efficient spraying and harvesting operations, (2) to maintain satisfactory light exposure for most of the leaves, and (3) to create a satisfactory balance between flowering and leaf surface.

To reduce hand labour costs, larger commercial fruit growers use machine pruning (Figure 11) on many types of fruits. Peach, apple, pear, and other fruits usually planted in hedgerows are mowed across the top and sides by machine, then thinned out as needed by a follow-up crew using pneumatic clippers and hand-powered saws, operating from hydraulically manipulated scaffolds or lifts of various types.

SOIL MANAGEMENT, IRRIGATION, AND FERTILIZATION

Soil management. Two soil management practices (1) clean cultivation and chemical weed control or both and (2) permanent sod culture, illustrate contrasting purposes and effects. In clean cultivation or chemical weed control, the surface soil is stirred periodically throughout the year or a herbicide is used to kill vegetation that competes for nutrients, water, and light. Stirring increases the decomposition rate of soil organic matter and thereby releases nitrogen and other nutrients for use by the fruit crop. It may also provide some improvement in water penetration. On the other hand, laying bare the soil surface exposes it to erosion; destruction of organic matter eventually lowers fertility and causes soil structure to change from loose and friable to tight and compacted. Though sod culture minimizes the destructive processes and may permit a modest increase in fertility, the sod itself competes with fruit plants for water and nutrients and may even compete for light. As a result, permanent sod culture is practical only with tree crops that are normally rather low in vegetation, such as apple, pear, sweet cherry, nuts, and mango. Competition from established sod may be detrimental to vigorously growing fruit plants like grape, peach, and raspberry unless adequate fertilizer and water are supplied.

Because each of these soil management systems has advantages and disadvantages, modifying or complementary practices are often used; for example, cover cropping, mulching, and chemical control of vegetation with or without strip sod in the row middles. In fact, the trend is toward mowed sod middles with strip chemical control under the trees and with overhead sprinklers during hot dry weather (Figure 11). Sprinklers not only provide water but tend to cool the plants and give fruit of better market quality without aggravating diseases. Cultivation combined with winter cover cropping has been used widely in grape, peach, cherry, bush fruit, and citrus plantings, as well as with other species. Mulching is the addition of undecomposed plant materials such as straw, hay, or processors' refuse to the soil under the plants. In orchards, mulching materials are most often applied under trees maintained in permanent sod. Strip in-row chemical control of vegetation in commercial fruit plantings has almost taken over as an economical and sound practice.

Sprinklers, cultivation, mulching

Irrigation. In semi-arid and arid regions, irrigation is necessary. Probably the maximum demand occurs in date gardens, because they expose a large leaf surface the year around under conditions of high evaporation and practically no rainfall. Irrigation in humid climates is generally being provided increasingly during extended dry periods that occur at one time or another during most growing seasons. For example, large acreages of banana are irrigated on coastal lowlands of the torrid tropics where annual rainfall exceeds 60 inches (1,500 millimetres) (see above *Irrigation and drainage*).

Fertilization. Needs of perennial fruit plants for fertilizers depend on the natural fertility of the soil supporting them and on their individual requirements. Of the essential elements, supplemental nitrogen is almost always needed; potassium supplements may be needed, even in some desert areas. Although strawberry, grape, peach, and a few other fruits have responded favourably to phosphorus, and although its application has been recommended, the phosphorus requirement of woody plants is low and deficiency is rather rare. Calcium deficiency may be more common than realized; lime is often desirable to reduce soil acidity and because of other indirect benefits. Inadequate magnesium in the soil has been noted by workers studying a wide range of fruit species. Of the trace elements, zinc, iron, and boron are most likely to be deficient, but copper, manganese, and molybdenum deficiencies also are being reported for some fruits in some regions. Iron deficiency is difficult to control in orchards where soils have high alkalinity. Granulated fertilizers in modern close-planted commercial orchards are usually broadcast by machine a month or two before growth starts. Additional nitrogen sometimes is applied in heavy crop years to apple, pear, and citrus.

CROP ENHANCEMENT

Pollination. The stimulus of pollination, fertilization, and seed formation is needed to get good size, shape, and flavour of most of the fruits. (Banana, pineapple, and some citrus and fig varieties are exceptions.) Transfer of pollen from the anthers (male) to the stigmas (female) is accomplished in nature either by insects or by movement in air. It is common practice to bring beehives into the orchard during bloom. Rainy cold weather during bloom with little or no sunshine can deter activity of the honey bee (the key insect pollinator) and reduce fruit set appreciably. This is one of the main problems not fully solved by fruit researchers. Hand-pollination by daubing collected and preserved pollen onto the stigma (as is done with date palms) sometimes is practiced for other fruits, but this approach is not widespread.

Thinning. Removal of flowers or young fruit (thinning) is done to permit the remaining fruits to grow more rapidly and to prevent development of such a large crop that the plant is unable to flower and set a commercial crop the following year. Thinning is done by hand, mechanically, or chemically. With the date, the pistillate flower cluster is reduced in size at the time of hand-pollination. In the case of certain table grape varieties, some clusters are cut off. With the Thompson seedless grape, a combination of girdling the trunk bark and judicious application of gibberellin (growth regulating) sprays at blossoming gives excellent full bunches.

Young peach fruits are thinned by striking the branches with a padded pole or by shaking the entire tree for a few seconds with a well-padded motor-driven shaker arm grasping the trunk. Hand thinning of young apple and peach fruits once was also a common practice, but because of the expense and difficulty, there has been increasing use of chemical sprays as a substitute. Two kinds of sprays are used: (1) mildly caustic sprays applied during bloom, such as Elgetol in arid regions, or (2) sprays of growth-regulating substances such as 3-CPA (2,3-chlorophenoxy propionamide) applied within a few weeks after bloom in areas with late frosts.

Pest control and preservation. In many fruit enterprises, pest control is the most expensive and time-consuming growing practice. Where the concentration of fruit farms in an area warrants it, individual efforts are complemented by legislative measures including quarantine regulations to force removal of pest-laden, unattended orchards. Sometimes the most economical control procedure is biological in nature. There is increased research today to find and multiply parasites that kill fruit crop pests. Such biological methods are necessary as political pressures increase for banning DDT and other chemicals. Selection of varieties that are immune, resistant to attack, or tolerant to specific

Biological pest control

pests, is a biological control procedure also widely used. Chemical control procedures, however, are relied on most heavily. Air-blast spray or mist-application machinery covering 70 acres (28 hectares) of trees or more in a day is now in common use (Figure 12).

HARVESTING AND PACKING

The proper time to remove a fruit from the tree or plant varies with each fruit and is governed by whether the product will be sold and consumed within hours, or stored for weeks, months, or even a year. Most fruits are harvested as close as possible to the time they are eaten. A few, of which banana and pear are outstanding examples, may be harvested while immature and still ripen satisfactorily. Orange, grapefruit, and some varieties of avocado may be "stored" on the tree for several months after they have attained good quality; this method cuts costs in handling and marketing.

Many fruits, including apple, pear, orange, lemon, and grapefruit, may drop from the tree during the last part of the maturation period. Preharvest drop of these fruits can be delayed by application of dilute sprays of growth-regulating substances like naphthaleneacetic acid (NAA). The chemical spray Alar [N-(dimethylamino) succinamic acid] applied four to six weeks after bloom on apple not only reduces fruit drop at harvest but increases red colour, firmness, and return bloom the next year, in addition to other advantages.

For the fresh market, most tree and bush fruits are still harvested by hand. For processing, drying, and occasionally for fresh market, mechanical motor-driven tree and bush shakers with appropriate catching belts, bins, pallets, and electric lifts reduce harvesting and handling labour. In years to come, machinery may make it possible to machine-harvest most fruits, with no more, and possibly less, damage than with hand picking (Figure 13).

The public is becoming increasingly particular about the appearance and quality of the product it buys. Hence, store managers and suppliers seek the best grades of fruits and nuts available, and growers make every effort to produce crops with attractive colour and smooth finish. Fruits are packed by government-controlled grades such as Fancy or Extra Fancy within given size limits and are so labelled on the carton or box, together with the source. Most fruits and nuts not meeting this standard of quality are processed or sent through channels using the lower grades and off sizes.

Small packages of plastic foam or wood pulp base holding four to six fruits covered and heat sealed with polyethylene plastic film are popular. These are delivered to stores in corrugated cartons holding a few dozen packages. Citrus, apples, and whole nuts or kernels also are packaged in polyethylene bags and delivered in cartons. Loose fruit may be sold in cell cartons and tray packs consisting of stacked form-fitting pulp trays in a "bushel size" box. Every effort is made to eliminate bruising.

Shipment in controlled atmosphere

Large truck-pulled containers with individually motor-driven refrigeration units, with or without controlled atmosphere (CO_2-O_2, to retard ripening), are loaded at the fruit source and trucked to their destination or are loaded on ships by derrick for overseas shipment. These sealed containers are also being used increasingly for bananas to reduce labour and handling and to deliver the product in better condition.

Air shipment of "vine- and tree-ripe" fruit (strawberries, figs, sweet cherries, pineapples, avocados) to distances as far as from California to Europe in a day or less is becoming increasingly common with the much larger and faster cargo planes and reduced air-freight prices.

POSTHARVEST PHYSIOLOGY OF FRUITS

Fruit ripening is a form of senescence and signifies the final stage in fruit development. A fleshy fruit is the enlarged ovary of a flower (avocado) or additional floral parts such as in apple, pear, and pineapple. Usually fertilization, and sometimes pollination alone, stimulate the floral parts causing a rapid cell division that leads to differentiation and the formation of the fruit structure. During this stage fruits consist of small, young cells filled with protoplasm. When the young fruit has been stimulated, presumably by plant hormones that originate from the embryonic seeds, rapid cell expansion takes place. During this stage fruits gain rapidly in size and weight. The cells develop small cavities or spaces in their tissue (become vacuolated) and begin the process of foodstuff accumulation, which lends fruits their compositional diversity. Banana, apple, and date, for example, accumulate mainly carbohydrates. Avocado and olive store fatty materials. Important constituents of most fruits are organic acids such as malic acid, found in apple and pear; citric acid, found in citrus fruits and pineapple; and tartaric acid, found in grapes. Fruits are usually low in protein.

Stages of ripening

After cell expansion has slowed and become nominal, fruits enter the stage of maturity and undergo preparation for ripening. Some crops, such as pear and avocado, are harvested at the so-called mature-green state and allowed to ripen afterward. Most fruits are at a stage of incipient ripening before they are picked. Ripening is marked by rapid and dramatic changes that give fruits their attractive and edible character. Some of the familiar changes are softening, which results from degradation of cell wall substances; disappearance of a green background, because of chlorophyll degradation (as in pear, apple, and banana); appearance of coloured pigments such as the carotenoids—orange-yellow—and anthocyanins—red (as in orange, mango, and strawberry); a decrease in acidity and increase in the sugar content (orange, apple); and emission of the volatile substances that give many fruits

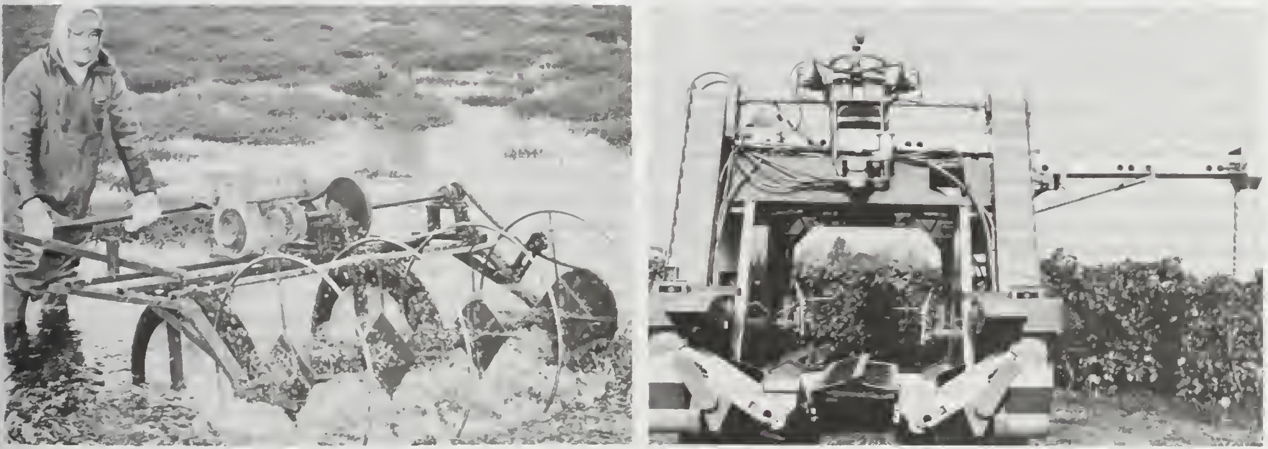

Figure 13: *Harvesting fruit mechanically.*
(Left) Cranberry harvester used on a bog to loosen and float berries. (Right) Grape harvester straddling a row of *Vitis vinifera* or *V. labrusca*. The grapes fall on belts and are carried on escalators to the top of the harvester where they enter the arm to be deposited (at right) in a tractor-pulled bulk bin for processing.

their distinct aroma (as in banana, pear, and apple). In climacteric fruits (*e.g.,* banana, pear, apple), ripening is accompanied by increased respiration. In nonclimacteric fruit (*e.g.,* strawberry, cherry) this phenomenon does not occur.

It is thought that the transition from the mature to the ripe stage is brought about by certain "ripening" enzymes. Protein molecules act as catalysts. The activity of these enzymes leads first to various ripening reactions, and then to gradual deterioration of the fruit tissue. Table 7 lists the major compositional changes in the edible fraction of several selected fruits.

Table 7: Major Compositional Changes in the Edible Fraction of Several Selected Fruits

constituent	content at maturity* (percent of fresh weight)	content upon ripening† (percent of content at maturity)
Apple		
Starch	2.0	5
Soluble sugars	7.5	99
Acids (malic)	1.0	60
Protein	0.2	120
Protopectin	0.7	12
Soluble pectin	0.2	160
Avocado		
Sugars	0.4	12
Fat	20.0	105
Protein	1.8	110
Banana		
Starch	20.0	6
Sugars	0.9	2,000
Protopectin	0.5	40
Soluble pectin	0.3	150
Orange		
Sugars	10.0	105
Acids (citric)	0.9	85
Pineapple		
Sugars	15.0	103
Acid	0.8	88

*"Content at maturity" means content when the fruit is normally harvested in mature but not necessarily ripe stage. †"Content upon ripening" refers to content at edible stage.

Because ripening leads to tissue breakdown, fruits are considered a highly perishable commodity. Different fruits have varying degrees of postharvest longevity. While strawberries last only a week to 10 days, for example, apples or lemons can be stored successfully for as long as several months.

Postharvest life of fruits can be extended by refrigeration with or without a modified oxygen–carbon dioxide atmosphere. Most temperate-zone fruits can be held safely at 32° to 41° F (0° to 5° C), but many subtropical and tropical fruits, including lemon, avocado, banana, and mango, show signs of injury from being chilled in prolonged cold storage and consequently fail to ripen properly. Bananas do not tolerate temperatures below 53° F (12° C), while several avocado varieties can be stored at temperatures as low as 46° F (8° C).

Fruit life can be extended further by both refrigeration and controlled atmosphere (CA) storage in which oxygen is kept at about 5 percent and carbon dioxide at 1 to 3 percent, while temperature is held at a level best suited to the particular fruit. So-called CA storage is common today for apples and pears and is being adapted to other fruits. Controlled atmosphere and refrigeration in conjunction with the removal of ethylene gas (which emanates from fruits and speeds ripening) helps slow the ripening process considerably. Golden Delicious apples and some pears are shipped in polyethylene containers in which a desirable, modified atmosphere is created by the respiring fruit.

Drying, canning, freezing

Drying is a standard practice for stabilizing the market movement of dates, figs, raisin grapes, prunes, and apricots. Canning is of paramount importance to the pineapple, peach, and pear industries (these fruits can be dried as well), and freezing is a means of stabilizing some of the most perishable fruits, including strawberry, raspberry, and blueberry.

Nuts are susceptible to mold, souring, staleness, discoloration, and rancidity. Cured and dried nuts are kept in prolonged cold storage under controlled temperature and humidity levels. Nuts also are stored and sold in vacuum packs of carbon dioxide-enriched atmosphere.

WASTE MATERIALS, OTHER USES

Apple wood is excellent for fireplace use, and cherry and certain other fruit woods are used for the finest household furniture. The dried residue from processing apples and citrus is made into feed for conditioning livestock for market, as are waste materials from many processed fruits. Apple pomace (waste material) is spread on the orchard floor with a manure spreader to help in soil conditioning and as a source of minerals.

Nutshells

Nutshells have many uses. Filbert shells are made into plywood, artificial wood, and linoleum; a mixture of shells with powdered coal and lignite makes cinder blocks; shells are used in making poisonous gases and gas masks, and as fuel and mulch. Cashew shell liquid, a skin irritant, is made into resins for varnishes; kills mosquito larvae; can be impregnated in wood as a varnish to preserve against insect attack; is used in automotive brake linings and clutch facings; is used as a laminating agent for paper, cloth, and glass fibres; and is used to treat cement floors and synthetic rubber to retard deterioration. Finely ground black-walnut-shell flour is used in plastic molding powder; as a glue extender; to prevent overheating of drills; to "sand"-blast jet engines; for polishing, burnishing, and deburring metal parts; for cleaning foundry molds; and to spray on tires for better traction. Pecan shells are used in place of gravel in cement walks and driveways; as fuel; as mulch and as a soil conditioner; in livestock bedding; as filler for fertilizers, feeds, etc.; in the manufacture of tanning agents, with charcoal and abrasives in hand soap; as a filler in plastic and veneer wood; and many of the same uses as black walnut shells. Some nutshells are made into beads, marbles, buttons, carving tools, ink, and ornament. The India clearing nut is cut open and rubbed on the inside of earthenware that will contain drinking water; the juice coagulates the water impurities which sink to the bottom. The nuts of the betel palm in the Far East and of the kola tree in West Africa are chewed for their stimulatory effects. (N.F.C.)

Livestock farming

Livestock is a general term that refers to all animals kept on a farm for use or for pleasure. In this section, the discussion of livestock includes both beef and dairy cattle, pigs, sheep, goats, horses, mules, asses, buffalo, and camels; the raising of birds commercially for meat or eggs (*i.e.,* chickens, turkeys, ducks, geese, guinea fowl, and squabs) is discussed below under *Poultry farming.* For further information on dairy-cattle breeds, feeding and management, see below, *Dairy farming.* For a discussion of the food value and processing of meat and dairy products, see the article FOOD PROCESSING. For a further discussion of Thoroughbred horses, see the article HORSES AND HORSEMANSHIP. Draft-horse breeds are discussed above under *Animal husbandry.*

An efficient and prosperous animal agriculture historically has been the mark of a strong, well-developed nation. Such an agriculture permits a nation to store large quantities of grains and other foodstuffs in concentrated form to be utilized to raise animals for human consumption during such emergencies as war or natural calamity. Furthermore, meat has long been known for its high nutritive value, producing stronger, healthier people.

Ruminant (cud-chewing) animals such as cattle, sheep, and goats convert large quantities of pasture forage, harvested roughage, or by-product feeds, as well as nonprotein nitrogen such as urea, into meat, milk, and wool. Ruminants are therefore extremely important; more than 60 percent of the world's farmland is in meadows and pasture. Poultry also converts feed efficiently into protein; chickens, especially, are unexcelled in meat and egg production. Milk is one of the most complete and oldest known animal foods. Cows were milked as early as 9000 BC. Hippocrates, the Greek physician, recommended milk as a medicine in the 5th century BC. Sanskrit writings from ancient India refer to milk as one of the most essential human foods.

CATTLE

Identifiable cattle breeds throughout the world number 277, with 33 generally classified as beef breeds, 18 as draft breeds, 39 as meat–draft, 54 as meat–dairy, 21 as dairy–draft, 61 as meat–dairy–draft, and 51 as dairy breeds. Most of these are quite limited in distribution and importance. No cattle are native to the North American continent, only bison, or buffalo. Cattle used for draft purposes are usually oxen—that is, castrated males at least two or three years old. Though long supplanted by the horse and the tractor in the developed countries, oxen are still used in Africa and tropical Asia.

In the U.S. today there are four times as many beef cattle as dairy cattle. Production of milk per dairy cow in the U.S. more than doubled after 1930 and reached 12,147 pounds (5,510 kilograms) in 1981. Elsewhere in the New World, the vast pampas of Argentina—an area as large as France—provide excellent conditions for grazing of cattle throughout the year without need for shelter. In Australia cattle have always ranked second in importance among livestock after sheep. Today's Australian beef cattle are raised mostly in the east and northeast portions of the continent, where feed and climate are unsuitable for sheep.

Beef cattle breeds. The British Isles led the world in the development of the principal beef breeds; Herefords, Angus, beef Shorthorns, and Galloways all originated in either England or Scotland. Other breeds of greatest prominence today originated in India (Brahman), France (Charolais; Limousin; Normandy), Switzerland (Simmental), and Africa (Africander). The Hereford breed, considered to be the first to be developed in England, probably descended from white-faced, red-bodied cattle of Holland crossed with the smaller black Celtics that were native to England and especially to Herefordshire. By the middle of the 18th century the slow process of selective breeding that resulted in the smooth, meaty, and prolific Herefords had begun. The United States statesman Henry Clay of Kentucky imported the first purebred Herefords to America in 1817.

British breeds

The Hereford, which became the most popular beef breed of the United States, is distinguished by its white face, white flanks and underline, white stockings and tail, and white crest on the neck. Its body colour ranges from cherry to mahogany red. It is of medium size, with present-day breeders making successful efforts to increase both its rate of weight gain and mature size, in keeping with the demand for cheaper, leaner beef.

The Polled Hereford is a separate breed of cattle originating from hornless mutations in 1901. It has the same general characteristics as the horned Hereford and has gained substantial favour because of its hornlessness and often faster rate of weight gain.

The Aberdeen Angus breed originated in Scotland from naturally hornless aboriginal cattle native to the counties of Aberdeen and Angus. Solid black, occasionally with a spot of white underneath the rear flanks, the breed is noted for its smoothness, freedom from waste, and high quality of meat.

Although the native home of the Galloway breed is the ancient region of Galloway in southwestern Scotland, it probably had a common origin with the Angus. The Galloway is distinguished by its coat of curly black hair. Though the breed has never attained the prominence of other beef breeds, it has been used extensively in producing blue-gray crossbred cattle, obtained by breeding white Shorthorn bulls to Galloway cows.

The beef, or Scotch, Shorthorn breed developed from early cattle of England and northern Europe, selected for heavy milk production and generally known as Durham cattle. These were later selected for the compact, beefy type by the Scottish breeders. Emphasis on leaner, high-quality carcasses in the second half of the 20th century has diminished the popularity of this breed. The Polled Shorthorn originated in 1888 from purebred, hornless mutations of the Shorthorn breed. The milking, or dual-purpose, Shorthorn, representing another segment of the parent Shorthorn breed, also was developed in England to produce an excellent flow of milk as well as an acceptable carcass, therefore resembling the original English type of Shorthorn. Shorthorns range in colour from red through roan, to white- or red-and-white-spotted.

The Brahman breed originated in India, where 30 or more separate varieties exist. Preference is given to the Guzerat, Nellore, Gir, and Krishna Valley strains, which are characterized by a pronounced hump over the shoulders and neck; excessive skin on the dewlap and underline; large, droopy ears; and horns that tend to curve upward and rearward. Their colour ranges from near white through brown and brownish red to near black. Their popularity in other areas such as South America and Europe, into which they have been imported, is attributable mainly to their heat tolerance, drought resistance, and resistance to fever ticks and other insects. The Santa Gertrudis was developed by the King Ranch of Texas by crossing Brahman and Shorthorn cattle to obtain large, hearty, tick-resistant, red cattle that have proved to be popular not only in Texas but in many regions along the semitropical Gulf Coast. Until the tick was eradicated in the southern and southwestern United States, Brahman crosses were raised almost exclusively there.

Several lesser breeds have been developed from crosses of the Brahman on other beef breeds such as: the Charbray (Charolais), Braford (Hereford), Brangus (Angus), Brahorn (Shorthorn), and Beefmaster (Brahman-Shorthorn-Hereford).

Cross-breeds

The Charolais breed, which originated in the Charolais region of France, has become quite popular in the United States for crossing on the British breeds for production of market cattle. The superior size, rate of gain, and heavy muscling of the pure French Charolais and the hybrid vigour accruing from the crossing of nonrelated breeds promise an increased popularity of this breed. Many American Charolais, however, carry significant amounts of Brahman blood, with a corresponding reduction in size, rate of gain, and muscling. Important in France, the Charolais is the foremost meat-cattle breed in Europe.

The Limousin breed, which originated in west central France, is second in importance to the Charolais as a European meat breed. Limousin cattle, often longer, finer boned, and slightly smaller than the Charolais, are also heavily muscled and relatively free from excessive deposits of fat.

The most prevalent breed of France, the Normandy, is smaller than the Charolais or Limousin and has been developed as a dual-purpose breed useful for both milk and meat production. A fourth important breed is the Maine–Anjou, which is the largest of the French breeds.

The Simmental accounts for nearly half of the cattle of Switzerland, Austria, and the western areas of Germany. Smaller than the Charolais and Limousin, the Simmental was developed for milk, meat, and draft. It is yellowish brown or red with characteristic white markings.

Beef cattle feed. Beef cattle can utilize roughages of both low and high quality, including pasture forage, hay, silage, corn (maize) fodder, straw, and grain by-products. Cattle also utilize nonprotein nitrogen in the form of urea and biuret feed supplements, which can supply from one-third to one-half of all the protein needs of beef animals. Nonprotein nitrogen is relatively cheap and abundant and is usually fed in a grain ration or in liquid supplements with molasses and phosphoric acid or is mixed with silage at ensiling time; it also may be used in supplement blocks for range cattle or as part of range pellets. Other additions to diet include corn (maize), sorghum, milo, wheat, barley, or oats. Fattening cattle are usually fed from 2.2 to 3.0 percent of their live weight per day, depending on the amount of concentrates in the ration and the rate at which they are being fattened. Such cattle gain from 2.2 to 3.0 pounds (1.0 to 1.4 kilograms) per day and require from 1.3 to 3.0 pounds (0.6 to 1.4 kilograms) of crude protein, according to their weight and stage of fattening. Up until the early 1970s, when the practice was prohibited, fattening cattle were given the synthetic hormone diethylstilbestrol as a supplement in their feed or in ear

Hormones for cattle

implants. The use of this synthetic hormone results in a 10 to 20 percent increase in daily gain with less feed required per pound of gain. Synthetic vitamin A sources have become so cheap as to permit the use of 10,000 to 30,000 International Units per day for cattle being fattened for market (finished) in enclosures bare of vegetation (drylots) used for this purpose. The economics of modern cattle finishing encourages the use of all-concentrate rations or a minimum of roughage, or roughage substitutes including oyster shells, sand, and rough plastic pellets. Corn (maize) silage produces heavy yields per acre at a low cost and makes excellent roughage for beef-cattle finishing.

Beef cows kept for the production of feeder calves are usually maintained on pasture and roughages with required amounts of protein supplement and some grain being fed only to first-calf heifers or very heavy milking cows. Most beef cows tend to be overnourished and may become excessively fat and slow to conceive unless they happen to be exceptionally heavy milkers. Most pregnant cows go into the winter in satisfactory condition and need to gain only enough to offset the weight of the fetus and related membranes. They can therefore utilize coarser roughages, having a total daily crude protein requirement of from 1.3 to 1.7 pounds (0.58 to 0.76 kilograms). Daily vitamin A supplement at the rate of 18,000 to 22,000 International Units per cow is advisable unless the roughages are of a green, leafy kind and the fall pasture has been of excellent quality. Feed requirements for bulls vary with age, condition, and activity, from 2.0 to 2.4 pounds of crude protein per day; from 25,000 to 40,000 International Units of vitamin A; and during breeding periods nearly the same energy intake as calves or short yearlings being finished for market, the main feeding requirement being to prevent their becoming excessively fat.

All cattle require salt (sodium chloride) and a palatable source of both calcium and phosphorus, such as limestone and steamed bone meal. Most commercial salts carry trace minerals as relatively cheap insurance against deficiencies that occasionally exist in scattered locations.

Beef cattle management. Beef production has become highly scientific and efficient because of the high cost of labour, land, feed, and money. Most brood-cow herds, which require a minimum of housing and equipment, are managed so as to reduce costs through pasture improvement and are typically found in relatively large areas and herds. Other aspects of management include performance testing for regular production of offspring that will gain rapidly and produce acceptable carcasses and the use of preventive medicine, feed additives, pregnancy checks, fertility testing of sires, artificial insemination of some purebred and commercial herds, protection against insects and parasites, both internal and external, adequate but not excessive feed intakes, and a minimum of handling.

Calving

Calving of beef cows is arranged to occur in the spring months to take advantage of the large supplies of cheap and high-quality pasture forages. Fall calving is less common and occurs generally in regions where winters are moderate and supplies of pasture forage are available throughout the year. Calves are normally weaned at eight to ten months of age because beef cows produce very little milk past that stage and also because they need to be rested before dropping their next calf. Feeder calves sell by the pound, so that weight for age is even more important than conformation or shape. Consequently, crossbred cattle are used; their hybrid vigour results in greater breeding efficiency and milk production on the part of the dam, as well as greater birth weight, vigour, and gaining ability on the part of the offspring.

Beef cows are normally first bred at 15 to 18 months. The gestation period is 283 days, and the interval between estrus, or periods in which the dam is in heat, is 21 days. Cows should produce a living calf every 12 months. Pasture breeding, in which nature is allowed to take its course, calls for one mature bull for every 25 cows, whereas hand breeding, in which control is exercised by the breeder, requires half as many bulls. Artificial insemination permits one outstanding sire to produce thousands of calves annually.

Diseases of beef and dairy cattle. Dairy cattle are susceptible to the same diseases as beef cattle. Many diseases and pests plague the cattle industries of the world, the more serious ones being prevalent in the humid and less developed countries. One of the more common diseases to be found in the developed countries is brucellosis, which has been controlled quite successfully through vaccination and testing. This disease produces undulant fever in humans through milk from infected cows. Leptospirosis, prevalent in warm-blooded animals and humans, is caused by a spirochete and results in fever, loss of weight, and abortion. Bovine tuberculosis has been largely eliminated; where it has not, it can infect other warm-blooded animals, including humans. Test and slaughter programs have proved effective. Rabies, caused by a specific virus that also can infect most warm-blooded animals, is usually transmitted through the bite of infected animals, either wild or domestic. Foot-and-mouth disease has been eliminated from most of North America, some Central American countries, Australia, and New Zealand. The rest of the world is still plagued by the disease, which attacks all cloven-footed animals. Humans are mildly susceptible to this organism. Successful vaccinations have been developed for blackleg, malignant edema, infectious bovine rhinotracheitis (or red nose), and several other diseases. Anaplasmosis, common to most tropical and semitropical regions, is spread by the bite of mosquitoes and flies. Anthrax, caused by a generally fatal bacterial infection, has been largely eliminated in the United States and western Europe. Rinderpest, still common to Asia and Europe, is caused by a specific virus that produces high fever and diarrhea. An infectious fever sometimes called nagana, caused by the tsetse fly, attacks both cattle and horses and is prevalent in central and southern Africa, as well as in the Philippines. Grass tetany and milk fever both result from metabolic disturbances. Bloat, caused by rapid gas formation in the rumen, or first compartment of the stomach, is sometimes fatal unless relieved. Pinkeye is an infectious inflammation of the eyes spread by flies or dust and is most serious in cattle having white pigmentation around one or both eyes. Mastitis, an inflammation of the udder, is caused by rough handling or by infection. Vibriosis, a venereal disease that causes abortion; pneumonia, an inflammation of the lungs; and shipping fever all cause serious losses and are difficult to control except through good management. Broad-spectrum antibiotics (antibiotics that are effective against various microorganisms), as well as powerful and specific pharmaceuticals, are effective and profitable means of keeping cattle herds healthy. Vermifuges, which destroy or expel parasitic worms, and insecticides, which kill harmful insects, are also highly effective and much used.

Mastitis

PIGS

Pigs are relatively easy to raise in confinement and can be slaughtered with a minimum of equipment because of their size and the many ways in which their carcasses can be processed into food and fat. Pigs are also quite efficient in converting feed to food.

Breeds. Pigs have a gestation period of 114 days with a 21-day interval between periods of estrus. A boar can mate with 15 to as many as 45 sows per year. The average litter consists of seven pigs, each with a birth weight of 2.5 pounds (1.1 kilograms). Sows should each produce 1.5 litters or more per year. Most market pigs are produced from crossbred sows by a boar of a third breed. There are more than 300 known breeds or local varieties of pigs throughout the world. A brief description follows of the better-known commercial breeds that have figured prominently in improving and upgrading domestic breeds and crosses throughout the world.

The Hampshire pig, which originated from the Norfolk thin-rind breed of England, is black with a white belt completely encircling its body and both front legs and feet. There should be no white on the head or the ham.

The Yorkshire pig, which originated early in the 19th century in England, where it was considered a bacon type, is long, lean, and trim with white hair and skin. Found in most countries, this breed is probably the most widely distributed in the world.

The Duroc-Jersey breed originated in the eastern United States from red pigs brought by Columbus and de Soto. The modern Duroc, originated from crosses of the Jersey Red of New Jersey and the Duroc of New York in the late 19th century, ranges from golden-red to mahogany-red in colour, with no black allowed. This breed proved particularly suitable for feeding in the U.S. Corn Belt (parts of Ohio, Indiana, Illinois, Wisconsin, Minnesota, South Dakota, Nebraska, Missouri, and Oklahoma; all of Iowa) and has been extensively used in Argentina, Canada, Chile, and Uruguay. The Poland China originated about 1860 in southern Ohio from a number of different breeds common to that area. The Spotted originated in Indiana about 1915 from crosses of the Poland China and the native spotted pigs. The Chester White, which originated in Chester County, Pennsylvania, after 1818, is restricted to the United States and Canada. The Berkshire, which originated in Berkshire, England, about 1770, is used for fresh pork production in England and Japan; a larger bacon type has been evolved in Australia and New Zealand. The Landrace is a white, lop-eared pig found in most countries in central and eastern Europe, with local varieties in Denmark, Germany, The Netherlands, and Sweden. World attention was first drawn to the Landrace by Denmark where, since 1890, by progeny testing (the selection of boars for breeding on the basis of the scientific assessment of their progeny), a superior pig, designed for Denmark's export trade in Wiltshire bacon to England, has been produced. Denmark no longer permits the export of Landrace for breeding. Sweden also has progeny tested from Landrace stock but for a shorter period. Pigs from Sweden were first exported to England in 1953, when prices of up to £1,000 were paid. This resulted in a worldwide Landrace explosion, and most major pig-producing countries have since taken stock.

The Landrace hog

The importance of the Asian pig breeds was recognized in the use of Chinese and "Siamese" pigs from southeastern Asia in the improvement of early European and North American breeds and is reflected in the name of the world-famous Poland China. China leads the world in pig numbers, and pork is traditional in the Chinese diet. Exports from China are substantial.

Feeding. Corn (maize) is a favourite feed for pigs, but wheat, sorghum, milo, barley, and oats also are used if the price is favourable. Wherever abundant and reasonable in price, soybean-oil meal is a favourite source of protein, and other oil meals and high-protein by-products are used in some countries. Antibiotics to control disease have become a standard ingredient in most pig rations. Improvements in breeding, disease control, management, and feed formulation have all contributed to faster gains and lower feed requirements per pound of weight gain. The use of antibiotics after World War II, especially in regions of less favourable sanitation, increased gain by as much as 20 percent.

Management. Pork production lends itself to mechanization and a minimum use of high-priced labour. The use of self-feeders and concentrated rations and construction of slotted floors and lagoons for waste disposal have become almost universal among large commerical producers in developed countries. Most commercial producers try to farrow pigs every two to three months of the year. Sows should have an 80 percent conception rate on first mating, ideally about eight or more pigs per litter, and average 1.6 litters per year. Most pigs are raised in confinement with various means of environmental control. Air-conditioned farrowing barns for excessively hot summers and heated floors and space heating or heat lamps for cold winters have become widespread.

Diseases. Pigs are subject to many infectious and parasitic diseases. Among the more common of these is transmissible gastroenteritis, an infectious disease often fatal to young pigs. Cholera, formerly controlled by vaccination, is now controlled by slaughter of infected animals. Leptospirosis, common to pigs as well as humans and most warm-blooded animals, can be controlled by vaccination. Necrotic enteritis and other infections of the intestinal tract are largely controlled by antibiotics. Atrophic rhinitis produces sneezing, crooked snouts, and unthriftiness (little or no weight gain even with proper feeding). Erysipelas, a bacterial infection of pigs, turkeys, and humans, causes in pigs inflammation of the skin, a swelling and stiffness of joints, and unthriftiness; it can be controlled through a vaccination program. Parasitic diseases are controlled mainly through effective sanitation programs and are less of a problem under confinement raising than when pigs are raised in the open. Effective vermifuges, which kill or expel parasitic worms, have been developed for further control. Production in the United States, the Scandinavian countries, and western Europe has been developed to a high state of efficiency, largely through effective control of infectious and parasitic diseases.

SHEEP

Sheep are able to subsist on sparse forage and limited water. Their wool is light in relation to its value and is relatively imperishable, both of which qualities enable wide exportation. During the 20th century, sheep-raising in some areas, particularly the western United States, has declined in favour of more profitable cattle.

Breeds. The gestation period for sheep is 147 days with 16.7 days between periods of estrus, which last 29 hours. The average number of lambs raised per hundred ewes is 91, and the average fleece weight per shearing is 8.34 pounds (3.78 kilograms).

Of more than 200 breeds of sheep in existence in the world, the majority are of limited interest except in the localities where they are raised. Sheep breeds are generally classified as medium wool, long wool, and fine wool. Of the medium wool breeds the Hampshire, Shropshire, Southdown, Suffolk, Oxford, and Dorset all originated in England. The Cheviot and Black Faced Highland originated in Scotland. The Panama, Columbia, and Targhee were developed in the United States, and the Corriedale in New Zealand. After World War II such larger breeds as the Suffolk and Hampshire increased in popularity at the expense of the smaller breeds.

The long wool breeds, including the Cotswold, Lincoln, Leicester, and Romney, were all developed in England and, in addition to mutton, produce wool of unusually long fibre length that is suitable for rugs and coarse fabrics.

Merino

The original fine-wool breed was the Merino, developed in Spain from stock native to that country before the Christian era. Though medieval Spain sought to preserve a monopoly on the Merino, the sheep gradually spread to France, Italy, and the rest of Europe. Today the Merino is prominent in Australia, the United States, Russia, South Africa, Argentina, France, and Germany; the breed is designated by various names such as Australian Merino in Australia and Merino Transhumante in Spain. The Merino was the main ancestor of the French Rambouillet, somewhat larger and less wrinkled than the Merino. This breed prospers in the western ranges of the United States, where two-thirds of that country's sheep are raised. The Corriedale breed, adapted to both farms and ranges, is especially valued in New Zealand and Australia. Most commercial sheep today represent two-breed or three-breed crosses, with white-faced crossbred ewes preferred in the range areas and a black-faced sire, such as Suffolk or Hampshire, preferred for market lambs, which are either finished for slaughter or sold as breeding ewes.

Feeding. Sheep are excellent foragers and, being ruminants, can utilize both pasture forage and harvested roughage. Selective in their grazing habits, they prefer short grass when available. Pregnant ewes can run on late pasture as long as it is available and abundant but in winter subsist satisfactorily on well-cured legume hay or mixed hay carrying a high percentage of legume. Corn (maize) silage is relatively inexpensive and relished by sheep; lactating ewes and lambs being finished for market usually require some concentrate, with corn (maize) favoured because of its high energy content and reasonable cost.

Range sheep grazing selectively on native plants frequently develop mild deficiencies of protein, energy, phosphorus, and vitamin A, especially when plants are mature or dormant or are eaten by ewes in the later stages of pregnancy or lactation. Broad spectrum antibiotics at the rate of five to 10 milligrams per pound of feed are normally used in all lamb finishing rations to prevent digestive disturbances and infections.

Management. Range sheep are normally white-faced crosses carrying both long-wool and Rambouillet breeding and are consequently very hardy and thrifty. They are wintered in bands, or flocks, of from 1,000 to 4,000 head at lower altitudes, and are moved in bands ranging from 1,000 to 1,500 head to summer range at much higher altitude, sometimes 300 miles (480 kilometres) from their winter quarters. Each flock is tended by a sheepherder and his dogs who move systematically from one grazing area to another. The herder often lives in a covered wagon or truck and may spend weeks at a time in complete solitude. The most famous sheepherders are the Basques, who emigrated widely from their home in Spain. The breeding ewes are mated to Suffolk or Hampshire rams and produce lambs during the late winter or early spring so that the lambs will be old enough to move to summer grazing without difficulty.

Shepherds

In many parts of the world small flocks are kept partly as scavengers to clean up fence rows, weeds, brush, and other undesirable forage, but this is a diminishing role. Large flocks are maintained partly for wool and partly for market lambs. Lambs are usually dropped in the spring and are sold at ages of from three to eight months and weights of around 40 pounds (18 kilograms) for Easter lambs, and 100 pounds (45 kilograms) for the usual market lambs. Sheep are sheared in the spring after the worst winter weather has passed. Some breeds are noted for producing a high percentage of twins, and others, such as the Dorset, for both high frequency of twins and heavy milk production. Shepherds frequently switch a newly born twin lamb to a ewe that has just lost a single lamb, thereby utilizing the extra milk. This practice requires skill and experience, since a mother ewe recognizes her own lamb by both its smell and the sound of its call.

Diseases. Such internal parasites as the tapeworm and several species of roundworms that infest the gastrointestinal tract are perhaps the greatest scourge of sheep, but modern vermifuges are quite effective against these. Dips are used to combat such external parasites as ticks, lice, and mites. Foot rot, caused by an infection of the soft tissue between the toes, results in extreme lameness and even loss of the hoof. The more persistent type is caused by a specific organism that is difficult to treat. The pain and the restricted movement of infected sheep result in rapid loss of weight. Enterotoxemia, or pulpy kidney, affects lambs at two to six weeks of age, especially those starting on unusually lush or rich feeds. A vaccination is quite effective in preventing this otherwise costly ailment.

GOATS

The goat has long been used as a source of milk, cheese, mohair, and meat. Its skin has been valued as a source for leather. In China, Great Britain, Europe, and North America, the goat is primarily a milk producer. By good management its limited (six months per year) breeding season and the consequent difficulty of maintaining a level supply of milk throughout the year, can be overcome. The goat is especially adapted to small-scale production of milk for the family table; one or two goats supply sufficient milk for a family throughout the year and can be maintained economically in quarters where it would not be practical to keep a cow.

Goat's milk

Pure-white goat's milk compares favourably with cow's milk in flavour and keeping qualities under sanitary conditions. It has certain characteristics differing from cow's milk that make it more easily digested by infants, invalids, and persons with allergies. Goat flesh is edible, that from young kids being quite tender and more delicate in flavour than lamb, which it resembles. Goat flesh is much prized in the Mediterranean countries, particularly in Spain, Italy, the south of France, and Greece. The Angora and Cashmere breeds are famous for their fine wool or mohair.

The many breeds may be roughly grouped: the prick-eared—*e.g.*, Swiss goats; the eastern, or Nubian, with long, drooping ears; and the wool goat—*e.g.*, Angora. While it is usually easy to distinguish goats from sheep, certain hair breeds of the latter are, to the layman, only distinguishable from goats by the direction of the tail, upward in goats, downward in sheep.

Of the Swiss goats, from which many of the best modern breeds are derived, the Toggenburg and Saanen are most important. The French breeds have much Swiss blood. In Germany the many varieties trace to Swiss breeds, which are also popular throughout Scandinavia and the Netherlands.

The Maltese goat, an important source of milk on the island of Malta, probably contains eastern blood. Many goats are found in Spain, northern Africa, and Italy, among them the Murcian, Granada, and La Mancha.

Nubians are African goats, chiefly Egyptian. They are usually large, short-haired goats with large lop ears and Roman noses. They may be of solid colour, parti-coloured, or spotted. The goats in Israel and Syria have long hair and large lop ears and most commonly are solid black or with white spots. Most Indian varieties, the best of which come from the Yamuna River area, have lop ears.

In Britain, the native goat was small, with short legs, long hair—usually gray but of no fixed colour—and with no definite markings. The widespread use of pedigree males, mostly of Swiss extraction, to improve the milk yield, has resulted in the almost total disappearance of the native types.

HORSES

Horses were among the last species of livestock to be domesticated. Domestication took place at least as early as 3000 BC, probably in the Near East. See also the article HORSES AND HORSEMANSHIP.

Breeds. The Arabian, the oldest recognized breed of horse in the world, is thought to have originated in Arabia before AD 600. Though its history is lost in the past, the breed probably descended from the Libyan horse, which, in turn, was probably preceded by horses of similar characteristics in Assyria, Greece, and Egypt as early as 1000 BC. The Arabian may be bay, gray, chestnut, brown, black, or white in hair colour, but always has a black skin. It ranges from 14.1 to 15.1 hands (4.7 to 5.0 feet, or 1.4 to 1.5 metres) in height. The Arabian horse has one lumbar vertebra less than other breeds of horse and is characterized by the high carriage of its head, long neck, and spirited action.

The Thoroughbred racing horse is descended from three desert stallions brought to England between 1689 and 1724; all of the Thoroughbreds of the world today trace their ancestry to one of these stallions.

The American Saddle Horse, which originated in the United States, was formed by crossing Thoroughbreds, Morgans, and Standardbreds on native mares possessing an easy gait. The American Saddle Horse is 15 to 16 hands (5 to 5.3 feet, or 1.5 to 1.6 metres) in height. Its colours are bay, brown, black, gray, and chestnut. There are two distinct types of the American Saddle Horse: three-gaited and five-gaited. The three natural gaits are walk, trot, and canter. Three-gaited saddle horses are shown with a short tail and cropped mane. They often have slightly less style and finish than the five-gaited horse. The five-gaited saddle horse has the three natural gaits plus two man-trained gaits—the rack and slow gait, or running walk. The American Saddle Horse is also used as a fine harness horse mainly for show.

Horse gaits

The American Quarter Horse traces to the Thoroughbred, and includes the blood of other breeds, such as the Morgan, the American Saddle Horse, and several strains of native horses. This fast, muscular horse has been raced, ridden in rodeos, and used for herding cattle.

The typical Quarter Horse is 15 to 16 hands tall and is of powerful build, suitable for both racing and the rough life of a cow pony. This horse is noted for its intelligence, easy disposition, and cow sense.

The Tennessee Walking Horse, or plantation horse, traces mainly to the Standardbred but also includes Thoroughbred and American Saddle Horse blood. The Tennessee Walking Horse is noted for its running walk, a slow-gliding gait in which the hind foot oversteps the print of the front foot by as much as 24 inches (600 millimetres). This breed is 15.2 to 16 hands high and is bay, black, chestnut, roan, or gray in colour.

The Morgan traces directly to "the Justin Morgan horse," foaled in 1793, of unknown breeding but no doubt tracing to Arabian stock. A dark bay in colour, Morgan stood 14 hands high and weighed 950 pounds (430 kilograms). He was a heavily muscled, short-legged horse of great style, quality, and endurance. He is the world's best example of prepotency, since he alone founded the Morgan breed. The Morgan is used for both riding and driving. It ranges from 14 to 16 hands in height and resembles the Arabian in size, conformation, quality, and endurance.

The American Standardbred originated around New York City during the first half of the 19th century from Thoroughbred, Morgan, Norfolk Trotter, Arabian, Barb, and pacers of mixed breeding. The modern Standardbred is smaller than the Thoroughbred, ranging from 15 to 16 hands in height and averaging about 15.2 hands. In racing condition it weighs from 900 to 1,000 pounds (410–450 kilograms). Stallions in stud condition average from 1,100 to 1,200 pounds (500–545 kilograms). Compared with the Thoroughbred, the Standardbred is longer-bodied, shorter-legged, heavier-boned, and stockier in build. Prevailing colours are bay, brown, and chestnut.

Draft horses

Draft horses have largely been supplanted by trucks and tractors in the developed countries of the world. Major draft breeds include the Percheron, developed in France; the Clydesdale of Scotland; the Shire of England; the Suffolk of England; and the Belgian of Belgium. These breeds range from 15½ to 17 hands in height at the withers; at maturity the mares weigh from 1,600 to 2,000 pounds (720–900 kilograms) and the stallions from 1,900 to 2,200 pounds (860–1000 kilograms).

The more popular pony breeds are the Shetland, which originated in the Shetland Islands, and the Hackney, of English origin. Ponies must be under 14.2 hands in height at the withers and are used both for show and for children's pleasure.

Feeding. The specific and exact nutrient requirements of horses are poorly understood. Usually, these may be supplied economically from pasture forage, harvested roughages, and concentrates. Good quality grass-legume pastures, in addition to iodized or trace-mineralized salt, will supply adequate nutrients to maintain an adult horse at light work (such as pulling a small cart) or mares during pregnancy. Lush, early spring pasture is very high in water and protein contents and may need to be supplemented with a high-energy source, such as grain, to meet the needs of horses performing medium to heavy work (such as plowing). Conversely, late fall- and winter-pasture forage is low in water and protein and may require protein and vitamin A supplementation. High-quality legume hays, such as early bloom alfalfa, are preferred for horses, especially those that are growing or lactating. Moldy or dusty feeds should be avoided because horses are extremely susceptible to forage poisoning and respiratory complications. Grass hays, such as timothy, prairie grass, orchard grass, and bluegrass, were preferred by early horsemen, especially for race horses, because they were usually free from mold and dust and tended to slow down the rate of passage through the intestinal tract. These hays are low in digestible energy and protein, however, and must be adequately supplemented. Silages of all sorts should be avoided since horses and mules are extremely susceptible to botulism and digestive upsets.

Oats are the preferred grain for horses because of their bulk. Corn (maize), barley, wheat, and milo can be used, however, whenever they are less expensive. Weanling foals require three pounds of feed per hundred pounds of live weight per day; as they approach maturity, this requirement drops to one pound of feed per hundred pounds of live weight daily. Horses normally reach mature weight at less than four years of age and 80 percent of their mature weight at less than two years of age.

A large and ever-growing number of horses stabled in cities and suburbs where sufficient roughages cannot be grown provide a large market for complete horse rations, including roughage, which are tailored to the total needs of specific animals according to their particular function at a given time, such as growth, pregnancy, lactation, or maintenance.

Horses will vary from the normal requirement in terms of weight, temperament, and previous nutrition. Foals will eat some pasture grass, forage, or hay when they are three days old and grain when they are three weeks old.

Management. Highly bred light horses are notoriously poor reproducers. Many horse farms consider a 60 percent foaling rate for a large band of mares to be average. Most large horse farms employ resident veterinarians to check for abnormalities or disease before breeding and to check mares for pregnancy 40 to 45 days after breeding. Because many mares conceive only every other year, expert assistance at foaling time is an absolute necessity, especially if the foal is sired by an expensive stallion out of a valuable mare.

Foaling mares

The gestation period of horses is 340 days. The period between estrus ranges from 18 to 28 days with an average of 22 days. Mature stallions can safely mate with from 50 to 100 mares per season, although the practice with expensive Thoroughbreds is to book no more than 35 to 40 mares.

The feet and legs of horses demand unusual attention. The old adage "no foot no horse" remains apt. Hooves should be trimmed regularly, beginning when the horse is a foal or only a few months old. Otherwise they may grow long and uneven, causing improper action, undue stress on joints, and broken or cracked hooves. Horses that are worked regularly, especially on hard and stony ground, as well as show horses and race horses in service, must be shod. Shod horses should have their hooves trimmed and their shoes refitted every four to six weeks. Tendency toward unsoundness is probably inherited but may be aggravated by poor hoof care and excessive stresses.

Diseases. Horses are especially susceptible to tetanus or lockjaw but can be given two-year protection through the use of a commonly accepted toxoid. There are two common types of abortion in horses: virus abortion, specifically viral rhinopneumonitis, and the *Salmonella* type. The former, which produces an influenza with pinkeye, catarrh, general illness, and abortion, affects both mares and foals, but all surviving horses develop natural resistance soon after infection. Pregnant mares thought to be subjected to infection may be given some protection by available vaccines. The *Salmonella* type of abortion can be prevented completely by vaccination. Encephalomyelitis, or sleeping sickness, is prevented by vaccination. A specific vaccine is available for anthrax, which is prevalent in Asia. Hemolytic anemia of foals has become a problem. Foals so afflicted are born normal but soon become sluggish and progressively weaker; the membranes of their eyes, mouth, and lips become very pale and the heartbeat becomes rapid. This condition is caused by antibodies in the mare's milk that destroy the foal's red blood cells. These antibodies are caused by the difference in blood type between the foal and the mother. Newborn foals can be muzzled to avoid nursing while their blood is checked for reaction against the serum and milk of its mother. Where reactions are noted, the mare is hand-milked at hourly intervals for 12 to 24 hours, and the foal is fed milk from another suitable mare or a milk substitute. Horses are quite susceptible to various infections, but rotation of pastures, strict sanitation, and the use of suitable vermifuges are quite effective.

ASSES AND MULES

The words donkey and ass are generally used interchangeably to denote the same animal, though ass is more often employed when the animal is wild and donkey is used for a domesticated beast. Wild asses inhabit arid, semidesert plains where the vegetation is sparse and coarse; the domestic donkey does well on coarse food and is hardy under rough conditions, hence its usefulness to man as a beast of burden in places where horses cannot flourish, such as the mountains of Ethiopia and other parts of northeast Africa, the high plains of Tibet, and the arid regions of Mongolia.

The donkey's occasional obstinacy in refusing work too heavy for it has become proverbial, but its equally proverbial stupidity has probably become legendary through its reaction to brutal treatment and neglect. It is naturally patient and persevering, responding to gentle treatment with affection and attachment to its master.

Mules are still used in some of the subtropical and tropical countries because of their ability to withstand most types of stress including heat, irregular feeding, and abuse. The mule is produced by crossing a jackass (*Equus asinus*) with a mare. The so-called Mammoth Jack was developed in America from European imports dating back to the late 18th century. It stands 15 to 16 hands (4.9 to 5.2 feet, or 1.5 to 1.6 metres) in height and weighs from 900 to 1,150 pounds (410–520 kilograms) at maturity. The reverse cross of a stallion on a jenny, or female ass, is called a hinny but theoretically has the same characteristics as a mule. At one time many different types of mules were recognized, such as draft mules, farm mules, sugar mules, cotton mules, and mining mules in declining order of size. The mining mule, a small, rugged individual weighing as little as 600 pounds (270 kilograms), was used in pit mines. These small mules are usually produced by pony dams.

Mining mules

Mules are surer-footed than horses and also more intelligent. For this reason they are still used as saddle and pack mounts in precarious terrain. Unlike horses, they also refuse to damage themselves by overeating or by thrashing around when tangled up or in cramped quarters.

BUFFALO AND CAMELS

Buffalo. The name buffalo is applied to several different cud-chewing (ruminant) mammals of the ox family (Bovidae). The true, or Indian, buffalo (*Bubalus bubalis*), also known as water buffalo, or arna, exists both as a wild and domestic animal; it has been domesticated in Asia from very early times and was introduced into Italy about the year 600. A large ox-like animal of massive and rather clumsy build with large horns that are triangular in cross section, the Indian buffalo, standing five feet (1.5 metres) at the shoulder, has a dull black body, often very sparsely covered with hair. The horns, which may be over six feet (1.8 metres) long, spread outward and upward, approaching each other toward the tips; they meet more or less in one plane above the rounded forehead and elongated face. Used for draft purposes, and also for milk and butter, the domesticated Indian buffalo is found throughout the warmer parts of the Old World from China to Egypt, and in Hungary, France, and Italy. Its cousin, the Cape, or African, buffalo (*Syncerus caffer*), a black animal of similarly massive build, has never been domesticated.

Camels. The term camel usually applies to two species of the genus *Camelus*. The Arabian camel, *Camelus dromedarius*, has one hump, the Bactrian camel, *Camelus bactrianus*, has two. The limbs are long and the feet have no traces of the second or fifth toes; the wide-spreading soft feet are well adapted for walking upon sand or snow. Horny pads on the chest and knees support the camel's weight when kneeling.

The Bactrian camel occurs throughout the highlands of Central Asia from Turkistan to Mongolia and is an important beast of burden throughout that region. The Arabian camel, characteristic of India, the Near East, and North Africa, is likewise primarily important as a beast of burden, though it also provides wool, milk, hides, and meat. It is longer-legged, shorter coated, and more lightly built than the Bactrian camel, standing about seven feet (2.1 metres) tall at the shoulder. In the 19th century camels were introduced to the U.S.–Mexico border regions, the Pacific Northwest, and Australia. The North American experiments were short-lived, but the animals were used in the exploration and development of the Australian outback until about 1940.

Camel diets

Camels can flourish on the coarsest of sparse vegetation, feeding on thorny plants, the leaves and twigs of shrubs, and dried grasses that other animals would refuse, though camels are not averse to more attractive food if it is available. When the feeding is good they accumulate stores of fat in their humps, upon which they are able to draw when conditions are adverse not only for sustenance but also for the manufacture of water by the oxidation of the fat; but they do not store water in the miscalled water cells. They are thus able to fast and go without drinking for several days; they have been known to go without water for 17 days and survive. Other adaptations that enable them to survive in deserts and other unfavourable environments include double rows of heavy protective eyelashes, haired ear openings, the ability to close their nostrils, and keen senses of sight and smell. The female produces one young at a birth after a gestation of 11 months and suckles it for a year; maturity is reached at the age of 10 to 12 years, and the life span is 30 to 40 years. (W.P.G.)

Dairy farming

Milk for human consumption is produced primarily by the cow and the water buffalo. The goat also is an important milk producer in China, India, Egypt, and in many Asian countries. Goat's milk is also produced in Europe and North America but, compared to cow's milk, goat's milk is relatively unimportant. Buffalo's milk is produced in commercial quantities in some countries, particularly India. Where it is produced, buffalo's milk is used in the same way as is cow's milk, and in some areas the community milk supply consists of a mixture of both. This section will treat the principles and practices of dairy farming. For a discussion of dairy products see the article FOOD PROCESSING.

DAIRY HERDS

Dairy cows are divided into five major breeds: Ayrshire, Brown Swiss, Guernsey, Holstein–Friesian, and Jersey. There are many minor breeds, among them the Red Dane, the Dutch Belted, and the Devon. There are also dual-purpose breeds used to produce milk and meat, notably the Milking Shorthorn and the Red Polled.

Breed characteristics

The Ayrshire breed originated in Scotland. Animals of this breed are red and white or brown and white in colour, and they are strong, vigorous, and good foragers. Ayrshire milk contains about 4.1 percent butterfat. Switzerland is the native home of the Brown Swiss. These cows are silver to dark brown in colour, with a black nose and tongue. Brown Swiss are strong and vigorous. The average fat test of the milk is 4.1 percent. The Guernsey breed originated on Guernsey Island off the coast of France. The Guernsey is fawn-coloured with clear white markings. The milk averages about 4.8 percent fat and has a deep yellow colour. The Holstein–Friesian breed originated in The Netherlands. It is black and white in colour and large in size. Holsteins give more milk than any other breed; the average butterfat content is 3.7 percent. The Jersey breed originated on the isle of Jersey, in Great Britain. Jersey cows are fawn in colour, with or without white markings. They are the smallest of the major dairy breeds, but their milk is the richest, containing on the average 5.2 percent butterfat. The protein content of milk is highest for Guernsey (3.91 percent) and Jersey (3.92 percent) and lowest for Holstein (3.23 percent).

Breeding and herd improvement. The breeds of dairy cattle have been established by years of careful selection and mating of animals to attain desired types. Increased milk and butterfat production has been the chief objective, although the objective often has shifted to increased milk and protein production. Production per cow varies with many environmental factors, but the genetic background of the cow is extremely important.

The principles of breeding to improve production have been helpful in increasing milk production in lesser developed countries. Progress has also been made in India with cows and water buffalo.

Artificial breeding has developed into a worldwide practice. Bulls with the genetic capacity to transmit high milk-producing ability to their female offspring are kept in studs. Dairy-farmer cooperatives usually operate the studs, with artificial insemination generally used. Semen for artificial insemination may be frozen for shipment to any part of the world.

Feeding dairy cattle. The dairy cow is an efficient producer of human food from roughage. This ability is attributable to a unique digestive system that consists of a four-compartment stomach capable of handling roughages not digested by human beings and other monogastric (one-stomached) animals.

Pasture is the natural feed for dairy cattle, and an abundance of good pasture provides most of the requirements of a good dairy ration. An outstanding example of grassland dairying is found in New Zealand, where cows are on pasture all year and milk production costs are at a minimum. The farmer does not need to prepare and store feed for a long winter period. Feeding a balanced ration, however, rather than grass alone, increases milk production. By 1981 the average annual production per cow in New Zealand was 7,189 pounds (3,261 kilograms) of milk, while in the U.S., where supplemental feeding is common, it was 12,147 pounds, or 5,510 kilograms. Pastures of poor quality must be supplemented with other feed, such as green crops, summer silage, or hay.

During seasons when pastures are inadequate, cows need hay, silage, and grain in sufficient amounts and balance to supply nutrient needs, and to guarantee a nutritional reserve to keep milk volume and composition from declining.

Disease prevention. Disease is one of the greatest problems of the dairy farm. It is a constant threat and may make removal of valuable animals from the herd necessary when they show even a possibility of disease. One study of removal of cows from a typical dairy herd showed that an average of 22 percent of cows were removed yearly and about a third of these were lost.

Herd management

Good herd management includes cleanliness, isolation of sick or injured animals, keeping premises free of hazards that might cause injury, and continuous protection against poisonous plants and other material. Certain diseases, such as tuberculosis, require injections. Others, such as mastitis, require constant treatment. For some diseases there is no known cure; slaughter of the animal is the only way to stop spread of the infection. Foot and mouth disease is the most notorious of these; severe measures have been employed by most governments in order to exclude or control this disease.

MILKING AND BULK HANDLING ON THE FARM

The development of milk-producing tissue in the mammae is triggered by conception; minimal production begins in the seventh or eighth week, but secretion is inhibited until after calving. The stimulus of calving increases lactation for several weeks, until another conception prompts a gradual decline. In response to pregnancy hormones and the needs of the fetus, the animal is usually dry for the month or two preceding calving. Milk is produced by the cow from her blood, and a large amount of food is necessary for maintenance of a high producing cow. The products of digestion and absorption enter the blood and are carried to the udder. There the raw materials are collected and changed into milk components. Each time the blood passes through the udder a small fraction of the components is removed to make the milk. Some 400 pounds (50 gallons, or about 200 litres) of blood must pass through the udder to make one pound (about 0.45 kilograms) of milk. A daily flow through the udder of 10 tons (20,000 pounds, or about 9,000 kilograms) of blood is required for a cow producing 50 pounds (22.5 kilograms) of milk per day. The energy required to produce milk components and to circulate the blood indicates the great importance of proper and abundant feed.

Use of milking machines

Today, most milking is done with machines by a carefully trained operator, usually twice a day, in stanchion barns or milking parlours. An experienced milker handles one to three machine units. The cows are first cleaned, and the teat cups put on. A pulsating vacuum draws the milk into a receiver or through piping into the farm milk tank (see Figure 14).

Milk is an extremely perishable commodity that must be cooled to 50° F (10° C) or less within two hours and must be maintained at that temperature until it is delivered to the consumer.

Milk is transported from farm to plant in a variety of ways, depending on the part of the world. In the Gujarat region of India, the milk is carried to a receiving station in jars on the heads of women who do the milking. The receiving station transports the milk in large cans to the plant by truck.

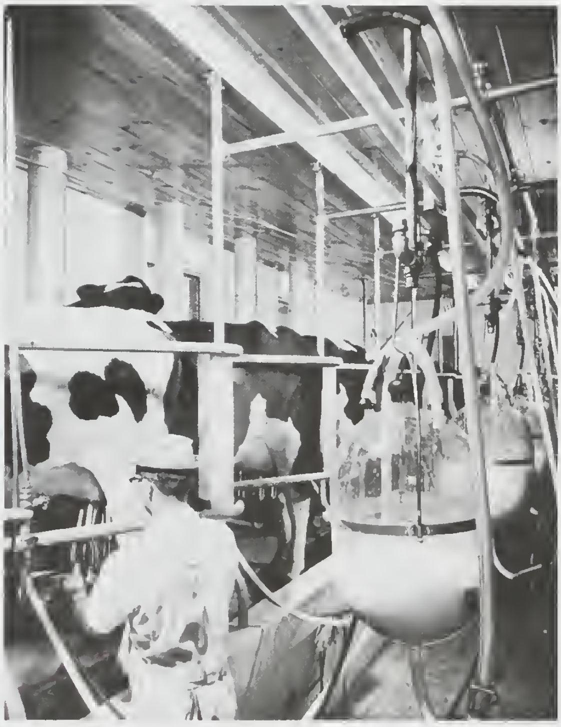

Figure 14: Attaching automatic milkers in a modern milking parlour in the United States.

Grant Heilman

In the major milk-producing countries of the world the milk is held cold in the farm tank or in cans until it is picked up, usually once or twice daily, by tanker or truck. Tankers pump the milk in at the farm and out into plant tanks on delivery. The tanker driver measures and samples each farmer's milk; fat and bacteria tests are run at the plant. The use of pipelines has been introduced on a small scale in some European countries for delivery of milk from farm to factory. (B.H.We./Ed.)

Poultry farming

This section will treat the principles and practices of poultry farming. For a discussion of the food value and processing of poultry products, see the article FOOD PROCESSING.

CHICKENS

Man first domesticated chickens of Indian origin for the purpose of cockfighting in Asia, Africa, and Europe. Very little formal attention was given to egg or meat production. Cockfighting was outlawed in England in 1849 and in most other countries thereafter. Exotic breeds and new standard breeds of chickens proliferated in the years to follow, and poultry shows became very popular. From 1890 to 1920 chicken raisers stressed egg and meat production, and commercial hatcheries became important after 1920.

Breeds. The breeds of chickens are generally classified as American, Mediterranean, English, and Asiatic. The American breeds of importance today are the Plymouth Rock, the Wyandotte, the Rhode Island Red, and the New Hampshire. The Barred Plymouth Rock, developed in 1865 by crossing the Dominique with the Black Cochin, has grayish-white plumage crossed with dark bars. It has good size and meat quality and is a good layer. The White Plymouth Rock, a variety of the Barred Plymouth Rock, has white plumage and is raised for its meat. Both varieties lay brown eggs. The Wyandotte, developed in 1870 from five or more strains and breeds, has eight varieties and is characterized by a plump body, excellent meat, and good egg production. Only the white strain is of any significance today because it is used in broiler crosses where its white plumage, quality of flesh, and rapid growth are highly desirable.

An American breed, the Rhode Island Red, developed in 1857 from Red Malay game fowl crossed with reddish-coloured Shanghais—with some brown Leghorn, Cornish, Wyandotte, and Brahma blood—is good for meat production and is one of the top meat breeds for the production of eggs. It has brilliant red feathers and lays brown eggs.

The New Hampshire, developed in the U.S. in 1930 from Rhode Island Red stock, is a meaty, early maturing breed with light-red feathers and lays large brown eggs. The only Mediterranean breed of importance today is the Leghorn. This breed, originated in Italy, has 12 varieties, the single-comb White Leghorn being more popular than all of the other types combined. This breed, the leading egg producer of the world, lays white eggs and is kept in large numbers in England, Canada, Australia, and the U.S. The White Minorca, a second Mediterranean breed, is often used in crossbreeding for egg production.

The only English breed of modern significance is the Cornish, a compact and heavily meated bird used in crossbreeding programs for broiler production. It is a poor producer of eggs, however.

The only Asiatic breed of significance today, the Brahma, which originated in India, has three varieties, the light Brahma being preferred because of its size.

Chicken breeding is an outstanding example of the application of basic genetic principles of inbreeding, linebreeding, and crossbreeding, as well as of intensive mass selection to effect faster and cheaper gains in broilers and maximum egg production for the egg-laying strains. Maximum use of heterosis, or hybrid vigour, through incrosses and crossbreeding has been made. Crossbreeding for egg production has used the single-comb White Leghorn, the Rhode Island Red, the New Hampshire, the Barred Plymouth Rock, the White Plymouth Rock, the Black Australorp, and the White Minorca. Crossbreeding for broiler production has used the White Plymouth Rock or New Hampshire crossed with White or Silver Cornish or incrosses utilizing widely diverse inbred strains within a single breed. Rapid and efficient weight gains, and high quality, plump, meaty carcasses have been achieved thereby.

Development of the egg

The male sperm lives in the hen's oviduct for two to three weeks. Eggs are fertilized within 24 hours after mating. Yolks originate in the ovary and grow to about 1.6 inches (4.0 centimetres) in diameter, after which they are released into the oviduct, where the thick white and two shell membranes are added. The egg then moves into the uterus where the thin white and the shell are added. This process requires a total of 24 hours per egg. The hatching of fertilized eggs requires 21 days, with the heavy breeds requiring a few more hours and the lighter breeds slightly fewer. Ideal hatching temperature approximates 100° F (38° C) with control of air flow, humidity, oxygen, and carbon dioxide being essential. Standardized egg-laying tests and official random sample tests have been used for many years to measure actual productivity.

Feeding. Chicken feeding is a highly perfected science that ensures a maximum intake of energy for growth and fat production. High quality and well-balanced protein sources produce a maximum amount of muscle, organ, skin, and feather growth. The essential minerals produce bones and eggs; 3 to 4 percent of the live bird being composed of minerals and 10 percent of the egg. Calcium, phosphorus, sodium, chlorine, potassium, sulfur, manganese, iron, copper, cobalt, magnesium, and zinc are all required. Vitamins A, C, D, E and K and all 12 of the B vitamins are also required. Water is essential, and antibiotics are almost universally used to stimulate appetite, control harmful bacteria, and prevent disease. Modern rations produce a pound of broiler on about two pounds (0.9 kilograms) of feed and a dozen eggs from 4½ pounds (2.0 kilograms) of feed.

Management. Among the world's agricultural industries, meat chicken breeding in the U.S. is one of the most advanced. It is presently considered the model for other animal industries, the broiler industry leading the way in advanced agricultural technology and efficiency. Intensive nutritional research and application, highly improved breeding stock, intelligent management, and scientific disease control have gone into the effort to give a modern broiler of uniformly high quality produced at ever-lower cost. Today, one person can care for 25,000 to 50,000 broilers that reach market weight in three months' time, giving an annual output of from 100,000 to 200,000 broilers. A modern broiler chick gains over 43 times its initial weight in an eight-week period. Aggressive marketing methods increased the per capita consumption of broilers more than fivefold in the three decades beginning in 1950, with further substantial increases predicted for the future. Less than half as much feed is now required to produce a pound of broiler meat as was needed in 1940. While per capita consumption of eggs has declined, the feed requirement per dozen eggs is only slightly more than half as high as it was in the early 1900s. Annual egg production per hen has increased from 104 to 244 since 1910.

Cages for laying

A carefully controlled environment that avoids crowding, chilling, overheating, or frightening is almost universal in chicken raising. Cannibalism, which expresses itself as toe picking, feather picking, and tail picking, is controlled by debeaking at one day of age and by other management practices. The feeding, watering, egg gathering, and cleaning operations are highly mechanized. More than 90 percent of the 4,200,000,000 chicks hatched per year in the early 1980s were used for broiler production and the remainder for egg production. In egg production feed represents more than two-thirds of the cost. Pullet (immature hen) flocks predominate. Hens are usually housed in wire cages with two or three hens per cage and three or four tiers of cages superposed to save space. Cages for laying hens have been found to increase production, lower mortality, reduce cannibalism, lower feeding requirements, reduce diseases and parasites, improve culling, and reduce both space and labour requirements.

OTHER POULTRY

These include turkeys, ducks, geese, guinea fowl, and squabs.

Turkey production. After World War II turkey production became highly specialized, with larger flocks predominating. Turkeys are raised in great numbers in Canada where their ancestors still live wild, as also in some parts of the U.S. Broad Breasted Bronze, Broad Breasted White, and White Holland are the most popular of the larger breeds, representing nearly three-fourths of the total production. The Beltsville Small White is the most popular of the smaller breeds and composes the bulk of the remaining 25 percent. At 24 weeks of age the toms are 50 percent heavier than the hens. In breeding flocks, one tom is required per eight or 10 hens. Tremendous improvements both in breeding and nutrition have been made in this century. Since 1910, the amount of feed required to produce a pound of turkey meat has fallen 40 percent, while the time required has been reduced 25 percent. Fifty to 80 pounds (23–36 kilograms) of feed will produce a turkey for market weight with from 2½ to 3 pounds required per pound of gain on full-size turkeys, and 2½ to 2¾ pounds (1.1–1.2 kilograms) of feed per pound (0.45 kilograms) of gain for turkey broilers, which are marketed at from 12 to 15 weeks of age. Turkey poults are hard to start on feed. One method is to dip their beaks in water and then in feed. Another is to light the feed troughs very brightly and to use oatmeal or ground yellow corn sprinkled on top of the feed. Turkeys are given range, or open land, and automatic waterers, self-feeders, range shelters, heavy fencing, and rotated pastures are used. Successful marketing techniques have increased turkey consumption; *e.g.*, in the U.S., per capita consumption from 1930/34 to 1980 rose 500 percent.

Duck and goose production. Duck raising is practiced on a limited scale in nearly all countries, for the most part as a small-farm enterprise. The flocks once kept in England are much reduced, the demand for eggs being greatly lessened, though a limited market still exists. Khaki Campbell and Indian Runner ducks are prolific layers, each averaging 300 eggs per year. In Indonesia, where the labour supply is large, duck herders take a flock of ducks to the high country during the warmer seasons and work their way down the mountainsides to the lowlands. Ducks

are easily transported, can be raised in close confinement, and convert some waste products and scattered grain (*e.g.*, by gleaning rice fields) to nutritious and very desirable eggs and meat. In developed countries, commercial plants have been built exclusively for duck meat production; an example is the large duckling industry of Long Island, New York. There are also local industries in The Netherlands and England, the favourite breed in England being the Aylesbury. This breed has white flesh and can reach eight pounds (3.6 kilograms) in eight weeks. The U.S. favourite is the Pekin duck, which is slightly smaller than the Aylesbury and yellow-fleshed.

Geese

Goose raising is a minor farm enterprise in practically all countries, but in Germany, Austria, some eastern European countries (notably Poland), parts of France, and locally elsewhere, there is important commercial goose production. The two outstanding meat breeds are the Toulouse, predominantly gray in colour, and the Embden (or Emden), which is white. Geese do not appear to have attracted the attention of geneticists on the same scale as the meat chicken and the turkey, and no change in the goose industry comparable to that in the others has occurred or seems to be in prospect. In some commercial plants, geese are fattened by a special process resulting in a considerable enlargement of their livers, which are sold as a delicacy, pâté de foie gras.

Guinea fowl and squabs. Guinea fowl are raised as a sideline on a few farms in many countries, and eaten as gourmet items. In Italy there is a fairly extensive industry. There the birds are raised in yards with open-fronted shelters. In England, guinea fowl are marketed at 16–18 weeks of age and in the U.S. at about 10–12 weeks. The market weight is usually about 2½–3½ pounds, but food conversion is poor.

Pigeons are raised not only as messengers and for sport but also for the meat of their squabs (nestlings), also a gourmet item. Squab production, carried on locally, is rare in most countries with established poultry industries.

POULTRY DISEASES

Poultry are quite susceptible to a number of diseases; some of the more common are fowl typhoid, pullorum, fowl cholera, chronic respiratory disease, infectious sinusitis, infectious coryza, avian infectious hepatitis, infectious synovitis, bluecomb, Newcastle disease, fowl pox, avian leukosis complex, coccidiosis, blackhead, infectious laryngotracheitis, infectious bronchitis, and erysipelas. Strict sanitary precautions, the intelligent use of antibiotics and vaccines, and the widespread use of cages for layers and confinement rearing for broilers have made it possible to effect satisfactory disease control.

Parasitic diseases of poultry, including hexamitiasis of turkeys, are caused by roundworms, tapeworms, lice, and mites. Again, modern methods of sanitation, prevention, and treatment provide excellent control. (W.P.G.)

Beekeeping

Beekeepıng is the care and management of colonies of honeybees. They are kept for their honey and other products or their services as pollinators of fruit and vegetable blossoms or as a hobby. The practice is widespread: honeybees are kept in large cities and villages, on farms and rangelands, in forests and deserts, from the Arctic and Antarctic to the Equator.

In antiquity people knew that bees produce delicious honey, that they sting, and that they increase their numbers by swarming. By the 17th century they had learned the value of smoke in controlling them and had developed the screen veil as protection against stings. From the 17th to the 19th century, the key discoveries upon which modern beekeeping is founded were made. These included the mystery of the queen bee as the mother of nearly all the occupants of the hive, her curious mating technique, parthenogenetic development, the movable frame hives, and the fact that bees rear a new queen if the old one disappears.

Given this knowledge people were able to divide a colony instead of relying on natural swarming. Then the development of the wax-comb foundation, the starter comb on which bees build straight, easily-handled combs, and the discovery that honey can be centrifuged or extracted from them and the combs reused, paved the way for large-scale honey production and modern commercial beekeeping. The identification of bee diseases and their control with drugs, the value of pollen and pollen substitutes in producing strong colonies, and the artificial insemination of queens have increased the honey-production efficiency of colonies.

HONEYBEES AND THEIR COLONIES

Honeybees. Honeybees belong to the order Hymenoptera and to one of the *Apis* species. (For a complete discussion of honeybees, see the article INSECTS: *Hymenoptera.*) Honeybees are social insects noted for providing their nests with large amounts of honey. A colony of honeybees is a highly complex cluster of individuals that functions virtually as a single organism. It usually consists of the queen bee, a fertilized female capable of laying a thousand or more eggs per day; from a few to 60,000 sexually undeveloped females, the worker bees; and from none to 1,000 male bees, or drones. The female of most species of bees is equipped with a venomous sting.

The queen

Honeybees collect nectar, a sugary solution, from nectaries in blossoms and sometimes from nectaries on the leaves or stems of plants. Nectar may consist of 50 to 80 percent water, but when the bees convert it into honey it will contain only about 16 to 18 percent water. Sometimes they collect honeydew, an exudate from certain plant-sucking insects, and store it as honey. The primary carbohydrate diet of bees is honey. They also collect pollen, the dustlike male element, from the anthers of flowers. Pollen provides the essential proteins necessary for the rearing of young bees. In the act of collecting nectar and pollen to provision the nest, the bees pollinate the flowers they visit. Honeybees also collect propolis, a resinous material from buds of trees, for sealing cracks in the hive or for covering foreign objects in the hive that they cannot remove. They collect water to air-condition the hive and to dilute the honey when they consume it.

A populous colony in a desirable location may, in a year's time, collect and carry into the hive as much as 1,000 pounds (450 kilograms) of nectar, water, and pollen.

Honeycomb

Bees secrete beeswax in tiny flakes on the underside of the abdomen and mold it into honeycomb, thin-walled, back-to-back, six-sided cells. The use of the cell varies depending on the needs of the colony. Honey or pollen may be stored in some cells, while the queen lays eggs, normally one per cell, in others. The area where the bees develop from the eggs is called the broodnest. Generally, honey is stored toward the top of the combs and pollen in cells around the broodnest below the honey.

The bees maintain a uniform temperature of about 93° F (34° C) in the broodnest regardless of outside temperature. The colony can survive daily maximum temperatures of 120° F (49° C) if water is available with which they can air-condition the cluster. When the temperature falls below about 57° F (14° C) the bees cease flying, form a tight cluster to conserve heat, and await the return of warm weather. They can survive for several weeks in temperatures of −50° F (−46° C).

When summer flowers bloom in profusion, the queen's egg-laying is stimulated, the cluster expands, and honey accumulates in the combs. When the large number of young bees emerge, the domicile becomes crowded.

Swarming. When the colony becomes crowded with adult bees and there are insufficient cells in which the queen can lay large numbers of eggs, the worker bees select a dozen or so tiny larvae that would otherwise develop into worker bees. These larvae are fed copiously with royal jelly, a whitish food with the consistency of mayonnaise, produced by certain brood-food glands in the heads of the worker bees. The cell in which the larva is developing is drawn out downward and enlarged to permit development of the queen. Shortly before these virgin queens emerge as adults from their queen cells, the mother queen departs from the beehive with the swarm. Swarming usually occurs during the middle of a warm day, when the queen and a portion of the worker bees (usually from 5,000 to 25,000) suddenly swirl out of the hive and into the air. After a few minutes' flight, the queen alights, preferably on a branch of a tree but sometimes on a roof, a parked automobile, or even a fire hydrant. All the bees settle into a tight cluster around her while a handful of scouts reconnoitre a new homesite.

When the scout bees have located a new domicile, the cluster breaks, the swarm takes to the air and in a swirling mass proceeds to the new home. Swarming is the bees' natural method of propagation or increase.

Queen bee. Back in the parent colony, the first queen to emerge after the mother queen departs with the swarm immediately attempts to destroy the others. If two or more emerge at the same time, they fight to the death. When the surviving virgin is about a week old, she soars off on her mating flight; she frequently mates with more than one drone while in the air. She may repeat the mating flights for two or three successive days, after which she begins egg laying. She rarely ever leaves the hive again except with a swarm. Normally, sufficient sperm are stored in her sperm pouch, or spermatheca, to fertilize all the eggs she will lay for the rest of her life. The drones die in the act of mating.

The queen can live up to five years, although many beekeepers replace the queen every year or two. If she is accidentally killed or begins to falter in her egg-laying efficiency, the worker bees will rear a "supersedure" queen that will mate and begin egg laying without a swarm emerging. She ignores the mother queen, who soon disappears from the colony.

Worker bees. Worker bees live about six weeks during the active season but may live for several months if they emerge as adults in the fall and spend the winter in the cluster. As the name implies, worker bees do all of the work of the hive, except the egg laying.

Drones. Drones are reared only when the colony is populous and there are plentiful sources of nectar and pollen. They usually live a few weeks, but are driven from the hive to perish when fall or an extended period of adversity comes upon the colony. The only duty of the drone is to mate with the queen.

The queen can lay drone (unfertilized) eggs in the drone cells. If she is not allowed to mate or if her supply of sperm is exhausted, she will lay unfertilized eggs in worker cells. The development of unfertilized eggs into adult drones is known as parthenogenesis. Occasionally a colony may become queenless and unable to develop another queen. Then, some of the worker bees begin to lay eggs, often several to a cell, and these develop into drones. A colony that has developed laying workers is difficult to requeen with a laying queen.

COLONY MANIPULATION

The yearly work cycle. The beekeeper's year starts in early fall. At that time he requeens the colonies whose queens are not producing adequate amounts of brood and makes sure that each colony has sufficient stores: at least 50 pounds (22 kilograms) of honey and several frames filled with pollen. Some beekeepers also feed the drug fumagillin to reduce possible damage to the adult bees by nosema disease (see below *Disease and pest control*). The colonies need a sunny exposure and protection from cold winds. Some beekeepers in northern and mountainous areas wrap their colonies with insulating material in winter. A few beekeepers kill their bees in the fall, harvest the honey, store the empty equipment, then restock with a two- or three-pound (0.8- or 1.4-kilogram) package of bees and a young queen the following spring.

Wintering

If the colonies are well prepared in the fall they need little attention during the winter. But in early spring, an examination of the colonies by the beekeeper is important. Frequently, strong colonies exhaust their food supply and starve only a few days before flowers begin to bloom in abundance. Only a few pounds of sugar syrup, 50-50 sugar water, or a honey-filled comb from another more prosperous colony might save such a starving colony. Again fumagillin may be fed to the colony, and some beekeepers also feed a cake of pollen substitute or pollen supplement. Honey is not fed to the colonies unless the beekeeper is sure about its source. Honey from colonies affected by the brood disease American foulbrood could infect his colonies and cause a serious loss.

As the spring season advances, the cluster size increases from the low population of 10,000 to 20,000 bees that survived the winter. To accommodate the increased size of the cluster and broodnest, the keeper adds more supers, or boxes of combs. If the combs are so manipulated that the queen can continually expand her egglaying area upward, the colony is unlikely to swarm. This can be achieved by placing empty combs or combs in which brood is about ready to emerge at the top of the cluster and combs filled with eggs or young brood toward the lower part of the broodnest. The beekeeper wants the colony to reach its peak of population, 50,000 to 60,000 bees, at the beginning of the major nectar flow.

The bees in a swarm, having departed the hive with a full stomach of honey, rarely sting. The usual way to capture them is to place a hive or upturned box beneath or nearby, then shake or smoke the bees to force the queen and a majority of the bees into it. The others follow. After the swarm is safely inside the box it can be removed to a permanent location.

Regulations governing the keeping of bees usually require the bees to be kept in hives with movable combs. If the bees are captured in a box they are generally transferred into a movable-frame hive within a few days so the new honey and comb will not be lost in the transfer.

Requeening a colony. When a beekeeper requeens a colony, he removes the failing or otherwise undesirable queen and places a new one in a screen cage in the broodnest. After a few days the colony becomes adjusted to her and she can be released from the cage. A strange queen placed in the cluster without this temporary protection usually will be killed at once by the workers. Queens usually are shipped in individual cages of about three cubic inches (50 cubic centimetres) with about half a dozen attendant bees and a ball of specially prepared sugar candy plugging one end of the cage. When the cage is placed in the hive, the bees from both sides eat the candy. By the time the candy is consumed and the bees reach each other, their odours have become indistinguishable, the queen emerges from the cage into the colony and begins her egglaying duties.

Beekeeping equipment. Standard tools of the beekeeper are: the smoker to quell the bees; a veil to protect the face; gloves for the novice or the person sensitive to stings; a blunt steel blade called a hive tool, for separating the frames and other hive parts for examination; the uncapping knife, for opening the cells of honey; and the extractor, for centrifuging the honey from the cells.

By courtesy of the U.S. Department of Agriculture

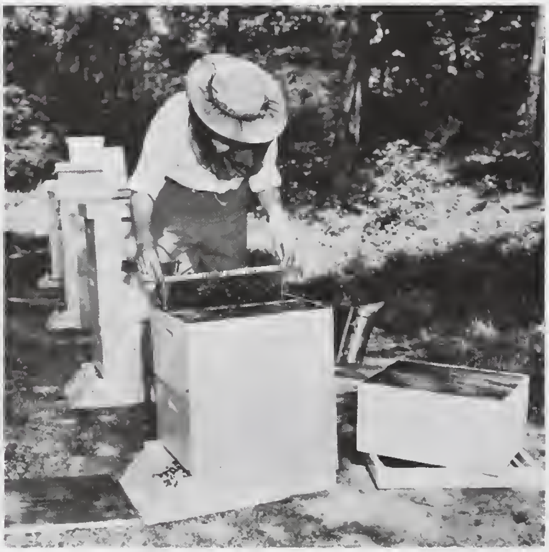

Figure 15: A beekeeper, wearing a veil and holding a hive tool, lifts a frame from a super. A smoker is attached to the side of the hive and a super has been removed.

Bee stings. The worker bee sting is barbed, and in the act of stinging it is torn from the bee. It has a venom-filled poison sac and muscles attached that continue to work the sting deeper into the flesh for several minutes and increase the amount of venom injected. To prevent this, the sting should be scraped loose (rather than grasped and pulled out) at once. Bee stings are painful, and no one becomes immune to the pain. Immunity to the swelling is usually built up after a few stings, however.

Reactions to stings

Normal reaction to a bee sting is immediate, intense pain at the site of the sting. This lasts for a minute or two and is followed by a reddening, which may spread an inch or more. Swelling may not become apparent until the following day. Occasionally, acute allergic reactions develop from a sting, usually with persons who have other allergic problems. Such a reaction becomes evident in less than an hour and may consist of extreme difficulty in breathing, heart irregularity, shock, splotched skin, and speech difficulty. Such persons should obtain the services of a medical doctor immediately.

BEE PRODUCTS

Honey production. Honey is marketed in several different forms: liquid honey, comb honey, and creamed honey. Sometimes the predominant floral type from which the honey was collected is indicated.

Liquid honey. If liquid (strained, extracted) honey is desired, additional supers are added directly above the brood nest. When one is largely filled, it is raised and another is placed underneath. This may continue until several have been filled, each holding from 30 to 50 pounds (14 to 23 kilograms), or until the nectar flow has ended. After the bees have evaporated the water until the honey is of the desired consistency and sealed in the cells, the combs are removed, the cells uncapped with the uncapping knife, and the honey extracted. The removed honey is immediately heated to about 140° F (60° C), which thins it and destroys yeasts that can cause fermentation. It is then strained of wax particles and pollen grains, cooled rapidly, and packaged for market.

Comb honey. In production of honey in the comb, or comb honey, extreme care is necessary to prevent the bees' swarming. The colony must be strong, and the bees must be crowded into the smallest space they will tolerate without swarming. New frames or sections of a frame with extra-thin foundation wax, added at exactly the right time for the bees to fill without destroying them, are placed directly above the brood nest. The bees must fill and seal the new comb to permit removal within a few days, or it will be of inferior quality. As rapidly as sections are removed, new sections are added, until the nectar flow subsides; then these are removed and the colony given combs to store its honey for the winter.

Creamed honey. Almost all honey will granulate or turn to sugar. Such honey can be liquefied without materially affecting its quality by placing the container in water heated to about 150° F (66° C). Liquid and granulated honey is sometimes blended, homogenized, and held at a cool temperature, which speeds uniformly fine granulation. If properly processed, the granules will be extremely fine; the honey, which has a smooth, creamy appearance, is referred to as creamed honey.

Floral types. Some honeys are sold by floral type; that is, they are given the name of the predominant flowers visited by the bees when they accumulated the honey. The beekeeper has no way to direct the bees to a particular source of food but through experience learns which plants are the major sources of honey. Different flowers produce different colours and flavours of honey. It may be heavy-bodied or thin-bodied, dark or light, mild-flavoured or strong-flavoured. Most honey has been blended by the beekeeper to a standard grade that can be supplied and marketed year after year.

Colour and flavour varieties

World honey production statistics. World production of honey was about 1,950,000,000 pounds (884,000,000 kilograms) in 1981. North America produced about 390,000,000 pounds (180,000,000 kilograms); the U.S.S.R., about 420,000,000 pounds (190,000,000 kilograms); and the remaining countries of the world, about 1,140,000,000 pounds (517,000,000 kilograms). The largest exporting countries were mainland China, Mexico, Argentina, and Australia. Although honey production per colony in the United States amounted to about 44 pounds (20 kilograms), when the colonies are properly manipulated and in good locations they frequently produce several times this amount. An average annual production of several hundred pounds per colony has been reported for a small isolated area of southwestern Australia.

Beeswax. Beeswax is a by-product of beekeeping in most areas. When beekeepers uncap or break honeycombs or have unusable combs, they try to salvage the beeswax. First, they recover as much honey from the combs as possible by drainage or extraction. Then they place the material in water heated to slightly over 145° F (63° C). This melts the wax, which rises to the surface. After it cools and hardens, the cake of wax is removed and refined for reuse in comb foundation. Beeswax has many other uses: in quality candles, cosmetics, agriculture, art, and industry. In some areas bees are manipulated primarily for wax production. Wax is a highly stable commodity that can be transported long distances under unfavourable conditions without damage.

Bees reared for sale. Queens are reared for sale to other beekeepers for requeening established colonies or for adding to a two- or three-pound (0.9- or 1.4-kilogram) package of 8,000 to 10,000 live bees to form new colonies or replenish weak ones. The queens are produced when the beekeeper cages the reigning queen in a colony, then inserts into the cluster from 30 to 60 queen cell bases into which young (one-day-old) worker larvae have been transferred. More than 1,000,000 queens are produced in this way and sold each year in the United States. Queens can be artificially inseminated with sperm from drones of a known source, but most beekeepers let the queens mate naturally.

The live bees are shaken from the combs of the colony through a funnel into screen-wire cages. About 500 tons of live bees are produced for sale annually in the United States, primarily in the southeastern states and California. Several tons are shipped annually from the United States to foreign countries, primarily to Canada.

Pollination. The greatest value of bees is in their service as pollinators. Some 90 crops grown in the United States alone are dependent on insect pollination, performed primarily by the honeybee. The average colony of bees is worth from 20 to 40 times as much in the pollination of crops as it is in the production of honey. The value of bees in the pollination of ornamental plants has never been calculated. Bees are also valuable in the pollination of some forest and range plants that produce seeds on which birds and other wildlife feed.

Bees in pollination

When bees are used in the pollination of crops, the beekeeper places the colonies within or adjacent to the field to be pollinated. The majority of the roughly 1,000,000 colonies that are used for pollination are used in alfalfa-seed fields and almond and apple orchards. The colonies are distributed at the rate of two or more per acre in groups every 0.1 mile (0.16 kilometre) throughout alfalfa fields. Two colonies per acre are recommended for almond orchards and about one colony per acre in apple orchards.

Some growers prefer to have the colonies placed alongside the orchard; others want them distributed in small groups within the orchard. Bees also are used regularly by growers of many other crops: blueberries, cantaloupes, cherries, clovers, cucumbers, cranberries, cutflower seed, plums and prunes, vetch, and watermelon.

DISEASE AND PEST CONTROL

Honeybees have diseases and enemies: diseases of the brood; diseases that affect only the adult bees; insect enemies of the adults and of the comb; and other enemies, including toads, lizards, birds, mice, skunks, and bears.

Diseases. American foulbrood, caused by a spore-forming bacterium, *Bacillus larvae,* is the most serious brood disease. It occurs throughout the world wherever bees are kept and affects workers, drones, and queens. The spores are highly resistant to heat and chemicals. A comb containing brood severely infected with this disease has a mottled appearance caused by the mixture of healthy capped brood interspersed with diseased or empty cells formerly occupied by diseased brood. The decayed mass has a typical ropiness when dug into, which is one of its identifying characteristics.

American foulbrood can be spread to healthy colonies by transferring equipment or allowing the bees to feed on honey from infected colonies. Sulfathiazole and Terramycin are widely used to control the disease. Many countries and most states in the U.S. require the destruction by fire of diseased colonies and have apiary inspectors to enforce the regulations.

European foulbrood is caused by a nonsporeforming bacterium, *Streptococcus pluton,* but *Bacillus alvie* and *Acromobacter eurydice* are often associated with *Streptococcus pluton.* This disease is similar in appearance to American foulbrood. In some instances it severely affects the colonies, but they recover so that colony destruction is not necessary. Terramycin can control the disease.

Sacbrood is caused by a virus and is superficially similar to the foulbrood diseases. It can appear and disappear spontaneously but is seldom serious. No chemical control is needed, but if the problem persists the beekeeper usually requeens the colony.

Chalk brood is caused by the fungus *Ascosphaera apis.* The larvae victims of this disease have a chalky, white appearance.

Stonebrood, which affects both brood and adults, is also caused by a fungus, *Aspergillus flavus,* which can usually be isolated from bees that have stonebrood.

Nosema disease

Nosema disease, caused by the protozoan *Nosema apis,* is the most serious disease of adult bees. It is widespread, causes heavy losses in honey production, and severely weakens colonies. The external symptoms of bees with nosema disease are not apparent. The disease is transmitted from adult to adult by ingestion of the spores that soon germinate in the ventriculus, or main, stomach. An infected ventriculus is normally swollen, soft, and grayish white. A degree of control may be obtained by feeding the colony the drug fumagillin.

Acarine disease is caused by the mite *Acarapis woodi* that gets into the tracheae of the bee through its breathing holes or spiracles in its thorax or midsection. Bees affected by this mite are unable to fly, have disjointed wings and distended abdomens. There is presently no good control for this mite. The only U.S. federal law pertaining to bees was passed to prevent the importation of adult bees carrying this mite into the United States. Two other mites, *Varroa jacobsoni* and *Tropilaelops clareae,* are serious problems of Asian beekeepers, but they do not occur in Europe or North America.

There are other minor diseases of adult bees, but they seldom cause serious problems.

Pests. The greater waxmoth, *Galleria mellonella,* is a lepidopterous insect that, in its larval stage, destroys combs. It does not attack adult bees, but may begin destruction of combs of a weak colony long before the bees are gone. It can also destroy stored combs of honey. When the larvae are ready to pupate they often eat out a place to spin their cocoons in the soft wood of the beehive, damaging frames and other hive parts. The best control for this pest is keeping colonies strong. Stored combs are fumigated, kept in a cold room or stacked in such a way that a strong air draft flows around them.

The larvae of the lesser waxmoth, *Achroia grisella,* cause damage to stored combs similar to that of the greater waxmoth. The Mediterranean flour moth larva, *Anagasta kuehniella,* feeds on pollen in the combs and causes some damage. Control for both of these moths is the same as for the greater waxmoth.

The bee louse, *Braula caeca,* is a tiny, wingless member of thc fly family that is occasionally found on bees, but feeds on nectar or honey from the mouthparts of its host. Its larvae burrow in the cappings of honey combs.

Ants sometimes invade hives and disrupt or kill the bees.

Termites can damage or destroy hive parts placed on the soil.

Other insects, such as dragonflies (Odonata), robberflies (Diptera), praying mantises (Orthoptera), ambush bugs (Hemiptera), and certain wasps and yellow jackets (Hymenoptera) are natural enemies of the honeybee.

Predators. Mice frequently enter the hive in winter when the bees are clustered, or they get into stored combs and despoil or damage them by chewing the frames and combs to construct their nest.

Skunks devour large numbers of bees at the hive entrance, usually at night. Fences, traps, and poison are used against them.

Bears eat the honeybees and brood in the hive, and usually destroy it and its contents in the process. In bear country, electric fences and traps are used to protect bee colonies.

Fighting among bees

At times bees become their own deadly enemy. If honey is exposed to them when no flowers are in bloom and the weather is mild, the bees from different colonies will fight over it. Sometimes this fighting, or robbing, becomes intense and spreads from hive to hive in moblike action. If all the bees in one colony are killed, the honey is quickly stolen and carried into other hives. This further intensifies the robbing so that a cluster that was carrying honey into its hive a few minutes earlier is attacked, all of its occupants killed, the honey again stolen and the process repeated. Usually, once robbing becomes intense, only darkness or foul weather will stop it. (S.E.McG.)

Cultivation of specialty crops

COTTON

Cotton, the seed fibre of a variety of plants of the genus *Gossypium,* belonging to the Malvaceae family, is the world's most important nonfood agricultural commodity. This section treats the cultivation of the cotton plant. For detailed information on the processing of cotton fibre and the history of its many uses, see the article INDUSTRIES, TEXTILE.

The cotton plant is normally cultivated as a shrubby annual in temperate climates but can be found as a perennial in treelike plants in tropical climates. The cultivated shrub grows from four to six feet tall (about one to two metres) over a growing period of six to seven months.

Factors influencing cotton crops

Warm and humid climates with sandy soil are the most suitable. Although cotton can be grown between latitudes 30° N and 30° S, yield and fibre quality are considerably influenced by climatic conditions, and best qualities are obtained with high moisture levels resulting from rainfall or irrigation during the growing season and a dry, warm season during the picking period. Rain or strong wind may cause damage to the opened bolls.

Within 80–100 days after planting, the plant develops white blossoms, which change to a reddish colour. The blossoms fall off after a few days and are replaced by small green triangular pods, called bolls, that mature after a period of 55–80 days. During this period the seeds and their attached hairs develop within the boll, which increases considerably in size. The seed hair, or cotton fibre, reaching a maximum length of about two and a half inches (approximately six centimetres) in long fibre varieties, is known as lint. Linters, fibres considerably shorter than the seed hair and more closely connected to the seed, come from a second growth beginning about 10 days after the first seed hairs begin to develop. When ripe, the boll bursts into a white, fluffy ball containing three to five cells, each having seven to 10 seeds embedded in a mass of seed fibres. Two-thirds of the weight of the seed cotton (*i.e.,* the seed with the adhering seed hair) consists of the seeds. To avoid damage by wind or rain the cotton is picked as soon as the bolls open, but since the bolls do not all reach maturity simultaneously, an optimum time is chosen for harvesting by mechanical means. Handpicking, carried out over a period of several days, allows selection of the mature and opened bolls, so that a higher yield is possible. Handpicking also produces considerably cleaner cotton; mechanical harvesters pick the bolls by suction, accumulating loose material, dust, and dirt, and cannot distinguish between good and discoloured cotton. A chemical defoliant is usually applied before mechanical picking to cause the plants to shed their leaves, thus encouraging more uniform ripening of the bolls.

Damage by insects and micro-organisms

Cotton is attacked by several hundred species of insects, including such harmful species as the boll weevil, pink bollworm, cotton leafworm, cotton fleahopper, cotton aphid, rapid plant bug, conchuela, southern green stinkbug, spider mites (red spiders), grasshoppers, thrips, and tarnished plant bugs. Limited control of damage by insect pests can be achieved by proper timing of planting and other cultural practices or by selective breeding of varieties having some resistance to insect damage. Chemical insecticides, which were first introduced in the early 1900s, require careful and selective use because of ecological considerations but appear to be the most effective and efficient means of control.

The boll weevil (*Anthonomus grandis*), the most serious cotton pest in the United States in the early 1900s, was finally controlled by appropriate cultivation methods and by the application of such organic insecticides as chlorinated hydrocarbons and organic phosphates. A species of boll weevil resistant to chlorinated hydrocarbons was recorded in the late 1950s; this species is combatted effectively with a mixture of toxaphene and DDT (dichlorodiphenyltrichloroethane), which has been outlawed in the United States and some other countries, however. The pink bollworm (*Pectinophora gossypiella*), originally reported in India in 1842, has spread throughout the cotton-producing countries, causing average annual crop losses of up to 25 percent in, for example, India, Egypt, China, and Brazil. Controls and quarantines of affected areas have helped limit the spread of the insect, and eradication has been possible in a few relatively small areas with sufficiently strict controls. The bollworm (*Heliothis zea,* also known as the corn earworm) feeds on cotton and many other wild and cultivated plants. Properly timed insecticide application provides fairly effective control.

Cotton plants are subject to diseases caused by various pathogenic fungi, bacteria, and viruses and to damage by nematodes (parasitic worms) and physiological disturbances also classified as diseases. Losses have been estimated as high as 50 percent in some African countries and in Brazil. Because young seedlings are especially sensitive to attack by a complex of disease organisms, treatment of seeds before planting is common. Some varieties have been bred that are resistant to a bacterial disease called angular leaf spot. Soil fumigation moderately succeeded in combatting such fungus diseases as fusarium wilt, verticillium wilt, and Texas root rot, which are restricted to certain conditions of soil, rainfall, and general climate. The breeding of resistant varieties, however, has been more effective. (H.-D.H.W.)

TOBACCO

Tobacco is the common name of the plant *Nicotiana tabacum* and, to a limited extent, *N. rustica* and the cured leaf that is used, usually after aging and processing in various ways, for smoking, chewing, snuffing, and extraction of nicotine. This section deals with the farming of tobacco from cultivation to curing and grading. For information on the history of tobacco cultivation and use and the manufacture of tobacco products, see the article TOBACCO in the *Micropædia*.

Cultivation. Though tobacco is tropical in origin, it is cultivated throughout the world. *N. tabacum* requires a frost-free period of 100 to 130 days from date of transplanting to maturity in the field. *N. rustica,* which is grown to some extent in India and certain Transcaucasian countries, matures in advance of *N. tabacum*.

The prime requisite for successful tobacco culture is a supply of well-developed, healthy seedlings that is available at the proper time for transplanting. Orinoco strains of seed are sown to grow leaf for flue curing. The Pryor group are grown to produce the dark air-cured and fire-cured types. Burley and Maryland strains are seeded for the production of light, air-cured tobaccos. Broadleaf and seed-leaf strains, Havana seed, Cuban, and Sumatra varieties are for the production of cigars. The variety grown for production of Perique resembles the Cuban-like variety used in Puerto Rico. Aromatic varieties are grown for production of this type of leaf and in some degree resemble the Cuban varieties.

Soil for a plant bed should be fertile and of good tilth and drainage; it must be protected from chilling winds and exposed to the sun. The soil is usually partially sterilized by burning, steaming, or using chemicals such as methyl bromide to control diseases, weeds, insects, and nematodes (a class of parasitic worms). In warm regions of the world the small germinating seedlings are produced outdoors in cold frames covered with thin cotton cloth or a thin mulch, such as chopped grass (used in particular in Zimbabwe), straw, or pine needles. Glass or plastic is used in colder regions, and close attention is given to watering and ventilation. The usual rate of seeding—*i.e.,* about one ounce (28 grams) of cleaned seed of high germination to 200 square yards (167 square metres) of seedbed area—can be expected, under favourable conditions, to produce 15,000 to 25,000 plants for transplanting. High-analysis mixtures of commercial fertilizers are usually applied before seeding at the rate of one-half to two pounds per square yard (0.3 to 1 kilogram per square metre) of seedbed area. The soil must be finely pulverized and level so that the seed can be lightly covered with soil by rolling or trampling. Uniform distribution of seeds is important. After eight to 10 weeks the seedlings are four to seven inches (10 to 18 centimetres) in length and are ready for transplanting in the field.

Transplanting machines are used extensively in some areas, but most of the world's tobacco is planted by hand. When the soil is dry, adding water helps a high percentage of transplants to survive. Fumigation of soil prior to transplanting is a common practice in many areas where nematodes are common; the process helps to reduce the damage caused by their parasitic activity.

Soil and fertilizer requirements vary widely with the type of tobacco grown. Well-drained soil with a structure that assures good aeration is desirable. Flue-cured, Maryland, cigar binder, and wrapper types of tobacco are produced on sandy and sandy-loam soil, with a sandy and sandy-clay subsoil where local conditions permit. Burley, dark air-cured, fire-cured, cigar-filler, and cigar-binder types are grown on silt-loam and clay-loam soils, with clay subsoils. The type of tobacco, soil, and climate determine fertilizer requirements. If any of the chemical elements essential for growth are lacking, the tobacco plant develops nutritional deficiency symptoms. Though nitrogen, phosphoric acid, and potash may be applied in the shade cigar-wrapper area of Florida–Georgia, very little fertilizer is used on eastern European fields of aromatic tobacco, where rich soils can make the leaf grow too large and rank to be desirable commercially.

Cigar-wrapper leaf

Soil must be prepared and cultivated to control weeds and promote the early and continuous growth of tobacco. For production of cigar-wrapper leaf, a unique method of

Eastfoto

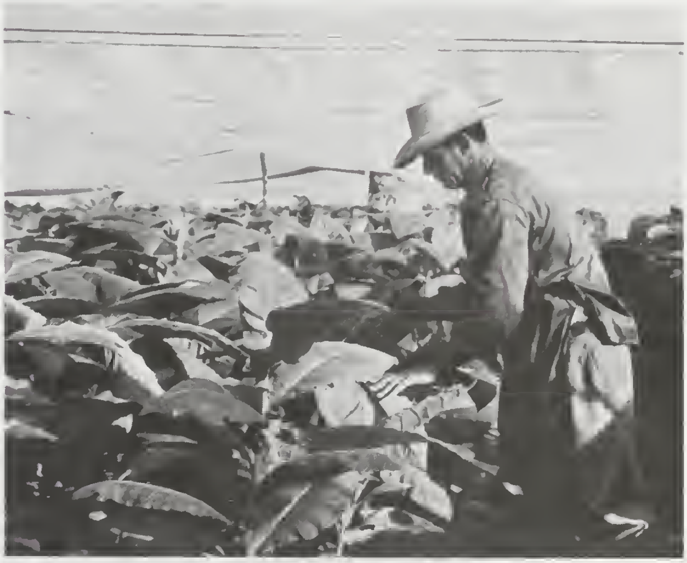

Figure 16: Tobacco cultivated under artificial shading cloth to produce leaves suitable for cigar wrappers, Cuba.

culture is practiced in Cuba and the United States, under artificial cheesecloth shade (see Figure 16). A high moisture content is maintained in soil and air to produce a thin, elastic leaf. In Sumatra and Java under the prevailing conditions of soil and climate, tobacco for cigar-wrapper is produced for one or two years following the clearing of jungle growth. Climatic and soil conditions characterized by a moist atmosphere appear to be associated with the production of acceptable cigar-wrapper tobacco. Cuban leaf for cigar filler is produced on certain soils from special varieties in the prevailing climatic conditions.

Aromatic tobacco culture in Turkey, in such Balkan countries as Bulgaria and Greece, and in certain other areas differs from that of most of the large-leafed tobaccos in that the plants are rarely topped and preferably are grown on soils of low productivity. The most acceptable aromatic leaf is produced in the Mediterranean climate, maturing during dry periods on upland soils.

Spacing of plants in the field varies widely according to the type of tobacco. Flue-cured tobacco rows are four feet (1.2 metres) apart, with plants 20 to 24 inches (50 to 60 centimetres) apart in the row. Burley and cigar tobaccos are three to 3½ feet (1.1 metres) by 15 to 27 inches (38 to 68 centimetres). Dark air-cured and fire-cured tobaccos may be planted on the square with hills 3½ feet apart. Maryland may be planted 32 to 36 inches (81 to 91 centimetres) or closer. Aromatic tobaccos are spaced in rows 15 to 24 inches (38 to 60 centimetres) apart, with three to eight inches (eight to 20 centimetres) between plants in the row. Perique is spaced the widest, with rows five feet (1.5 metres) apart and 36 to 42 inches (91 to 107 centimetres) between plants.

Topping

Large-leaf tobaccos grown in the United States and in several other countries are topped—that is, the terminal growth is removed—when the plant has reached the desired size, usually at or shortly after flowering. The number of leaves remaining varies widely. Dark air-cured and fire-cured tobaccos may have 10 to 16 leaves; Burley, flue-cured, Maryland, and cigar types may have 16 to 20 leaves. After topping, the suckers, or lateral shoots, are removed to increase leaf development, providing increased yields. The work may be done by hand, in which case it must be repeated regularly, or by application of sucker-suppressing chemicals.

Diseases and pests. Common diseases and pests are black root rot, fusarium wilt, tobacco mosaic, bacterial leaf spot, downy mildew or blue mold, black shank, broomrape, and witchweed. These may be controlled by sanitation, crop rotation, the use of sprays and fumigants, and breeding of disease-resistant strains. Resistance to bacterial leaf spot, fusarium wilt, mosaic, black shank, and black root rot have been accomplished by breeding. Some resistant varieties of tobacco in general use have been produced by blending desired characteristics from *N. longiflora, N. debneyi, N. glutinosa,* and others with some strain of *N. tabacum.*

Common insect pests are the green June beetle larvae, cutworms, and flea beetles in the plant bed and hornworms, grasshoppers, flea beetles, cutworms, budworms, and aphids in the field. The cigarette, or tobacco, beetle damages the stored leaf and sometimes the manufactured product. Insect pests are controlled on the growing crop by using sprays and dusts, on the stored product by fumigating and trapping. Biological control often is effective. Fumigation controls nematodes in the field.

Harvest. Tobacco is harvested 70 to 130 days after transplanting by one of two methods: (1) the entire plant is cut and the stalk split or speared and hung on a tobacco stick or lath, or (2) the leaves are removed at intervals as they mature. The leaves of cigar-wrapper and aromatic tobaccos are strung using a needle, and leaves to be flue-cured are looped, using a string tied to a lath or stick that is hung in the curing barn. To prevent breakage and bruising during the handling necessary in curing, it is desirable for the leaf to wilt without sunburning. Tobacco may be left in the field from a few hours to two days to wilt.

Curing. The three common methods of curing are by air, fire, and flue. A fourth method, sun curing, is practiced with aromatic types and to a limited extent with air-cured types. Curing entails four essential steps: wilting, yellowing, colouring, and drying. These involve physical and chemical changes in the leaf and are regulated to develop the desired properties. Air curing (see Figure 17) is accomplished mainly by mechanical ventilation inside buildings. Coke, charcoal, or liquid petroleum gas may be burned to provide heat when conditions warrant. Air curing, which requires from one to two months' time, is used for many tobaccos, including dark air-cured types, cigar, Maryland, and Burley.

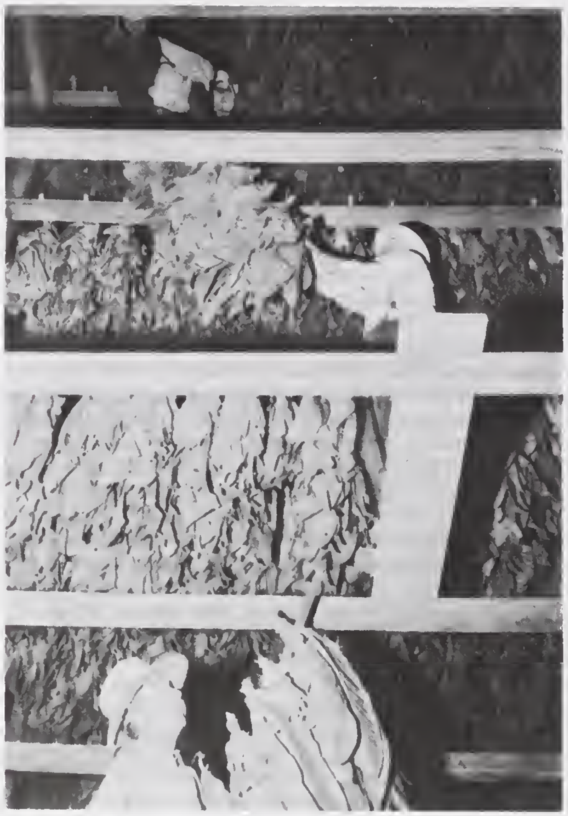

Figure 17: Hanging Maryland tobacco, cured on the stalk, in a curing barn.

By courtesy of the U.S. Department of Agriculture

Air curing, fire curing, and flue curing

The fire-curing process resembles air curing except that open wood fires are kindled on the dirt floor of the curing barn after the tobacco has been hanging for two to six days. The smoke imparts to the tobacco a characteristic aroma of creosote. The firing process may be continuous or intermittent, extending from three weeks to as long as 10 weeks until curing is complete and the leaf has been cured to the desired finish.

The barns for flue curing are small and tightly constructed with ventilators and metal pipes, or flues, extending from furnaces around or under the floor of the barn. Fuels used are wood, coal, oil, and liquid petroleum gas. If oil or gas heaters are used, flues are not needed. Heat is applied carefully, and the leaves are observed closely for changes in their chemical and physical composition. Flue curing requires from four to eight days' time and is used for Virginia, or bright, tobacco. In the process called bulk curing, the leaves are loaded evenly in racks arranged in a curing chamber.

Grading. After curing, the leaf may be piled in bulk to condition for a time before it is prepared for sale. The preparation consists usually of grading the leaf and putting it in a bale or package of convenient size and weight for inspection and removal by the buyer. Except during humid periods, the leaf must be conditioned in moistening cellars or humidified rooms before it can be handled without breakage. Type of leaf and local custom determine the fineness of grading. At its most elaborate, grading may be by position of the leaf on the plant, colour, size, maturity, soundness, and other recognizable qualities; flue-cured tobacco in the United States and Zimbabwe is graded this way, and each grade bulked or baled separately. Much simpler grading is usual in developing countries, where the buyer is as much concerned with the proportions of each grade as with the quality of the entire lot; aromatic tobaccos are an example of this. Most tobaccos entering world trade, except the aromatic, are assembled before sale into bundles, or hands, of 15 to 30 leaves and tied with one leaf wrapped securely around the butts.

Forced aging

Most tobaccos, except aromatic and cigar, are regraded if necessary and usually redried after purchase; then the exact amount of moisture needed for aging is added and the tobacco is securely packed in cases or hogsheads. Exported tobacco is shipped in this form. The trend is for the packing factories to stem the leaf—that is, remove most of the stem leaving the lamina—usually by threshing machines but sometimes by hand, before redrying it. The aging process, particularly with cigar tobaccos, is sometimes hastened by forced fermentation procedures. After purchase, aromatic tobaccos are manipulated; that is, they are factory-graded, baled, and subjected to an elaborate, in-the-bale, fermentation process before going to the ultimate manufacturer. (J.E.McM.)

TEA

The tea plant, a species of evergeen (*Camellia sinensis*), is cultivated for its young leaves and leaf buds, from which the tea beverage is produced. This section treats the cultivation of the tea plant. For information on the processing of tea and the history of its use, see the article BEVERAGE PRODUCTION.

Varieties. The natural habitat of the tea plant is considered to be within the fan-shaped area between the Nāgāland, Manipur, and Lushai hills along the Assam–Myanmar (Burma) frontier in the west; through to China, probably as far as Chekiang province in the east; and from this line south through the hills of Myanmar and Thailand into Vietnam. The three main varieties of the tea plant, China, Assam, and Cambodia, each occur in their most distinct form at the extremes of the fan-shaped area. There are an infinite number of hybrids between the varieties; such crosses can be seen in almost any tea field.

The China variety, a multistemmed bush growing as high as nine feet (2.75 metres), is a hardy plant able to withstand cold winters and has an economic life of at least 100 years. When grown at an altitude near that of Darjeeling and Sri Lanka (Ceylon), it produces teas with valuable flavour during the season's second flush or growth of new shoots.

The Assam variety, a single-stem tree ranging from 20 to 60 feet (six to 18 metres) in height and including several subvarieties, has an economic life of 40 years with regular pruning and plucking. The tea planter recognizes five main subvarieties: the tender light-leaved Assam, the less tender dark-leaved Assam, the hardy Manipuri and Burma types, and the very large-leaved Lushai. In Upper Assam, the dark-leaved Assam plant, when its leaves are highly pubescent, produces very fine quality "golden tip" teas during its second flush. (The Chinese word *pekho*, meaning "white hair" or "down," refers to the "tip" in tea, which is correlated with quality.)

The Cambodia variety, a single-stem tree growing to about 16 feet (five metres) in height, is not cultivated but has been naturally crossed with other varieties.

The mature leaves of the tea plant, differing in form according to variety, range from 1½ to 10 inches (3.8 to 25 centimetres) in length, the smallest being the China variety and the largest the Lushai subvariety. In harvesting, or plucking, the shoot removed usually includes the bud and the two youngest leaves. The weight of 2,000 freshly plucked China bush shoots may be one pound (0.45 kilogram); the same number of Assam shoots may weigh two pounds (0.9 kilogram). Tea leaves may be serrated, bullate, or smooth; stiff or flabby; the leaf pose ranges from erect to pendant; and the degree of pubescence varies widely from plant to plant.

Cultivation. Three considerations in planning a tea estate are climate, soil acidity, and labour availability.

A suitable climate has a minimum annual rainfall of 45 to 50 inches (1,140 to 1,270 millimetres), with proper distribution. If there is a cool season, with average temperatures 20° F (11° C) or more below those of the warm season, the growth rate will decrease and a dormant period will follow, even when the cool season is the wetter one.

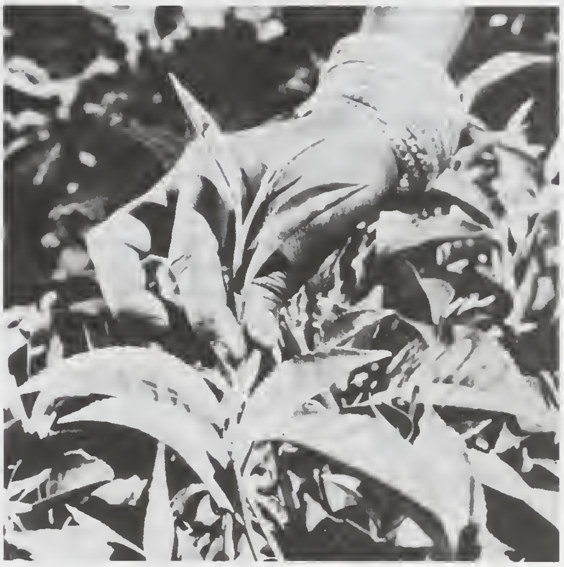

Figure 18: A tea shoot comprising a bud and two leaves being plucked by hand in Sri Lanka.
By courtesy of the Ceylon Tea Bureau, London

Tea soils must be acid; tea cannot be grown in alkaline soils. A desirable pH value is 5.8 to 5.4 or less. A crop of 1,500 pounds of tea per acre (1,650 kilograms per hectare) requires 1.5 to 2 workers per acre (3.7 to 4.9 workers per hectare) to pluck the tea shoots and perform other fieldwork. Mechanical plucking has been tried, but because of its lack of selectivity, cannot replace hand plucking.

The scientific study of tea

Scientific study of tea production began about 1890. Most tea-producing countries maintain scientific research stations to study every aspect of the subject, including seed production, clonal selection (for the propagation of single leaf cuttings), tea nursery management, transplanting, development of the bush and subsequent pruning and plucking, soil management and fertilizer use, and the ultimate replanting of the stand. Although procedures in all countries are related, appropriate details must be determined for each area. Since 1900, advancements in tea cultivation have increased the average yield per acre in Assam from 400 to 1,000 pounds (180 to 450 kilograms), with many estates producing over 1,500 pounds (680 kilograms).

Pests and diseases. The tea plant is subject to attack from at least 150 insect species and 380 fungus diseases. In northeast India, where 125 pests and 190 fungi have been detected, losses from pests and diseases have been

By courtesy of Brooke Bond Oxo Ltd

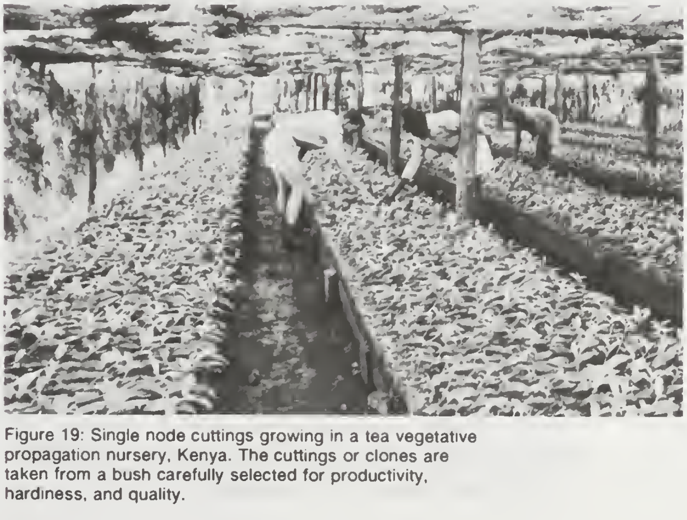

Figure 19: Single node cuttings growing in a tea vegetative propagation nursery, Kenya. The cuttings or clones are taken from a bush carefully selected for productivity, hardiness, and quality.

estimated at 67,000,000 pounds (30,000,000 kilograms) of tea per annum. More than 100 pests and 40 diseases occur in the tea fields of Japan. Sri Lanka, where estates are close together or contiguous, has recorded many blights and suffered serious losses. Africa has little trouble with blights; the tea mosquito (*Helopeltis theivora*) is the only serious pest. The Caucasus, with a climate similar to that of Japan, grows the China variety of plant and has no serious pests or blights.

Blight control has become highly developed. Northeast Indian scientists have issued a list of 40 approved proprietary pesticides. Some of these pesticides cannot be applied during the plucking season; others require that the two subsequent rounds of weekly pluckings be discarded.

(C.R.H.)

BIBLIOGRAPHY

General works. C.B. RICHEY (ed.), *Agricultural Engineers' Handbook* (1961), though dated, is still a useful reference on crop-production equipment, soil and water conservation, and farm buildings. More recent treatments include *Primrose McConnell's The Agricultural Notebook,* 18th ed. edited by R.J. HALLEY and R.J. SOFFE (1988), on all aspects of farming, with special emphasis on practices in the United Kingdom; and GORDON WRIGLEY, *Tropical Agriculture,* 4th ed. (1982), on crop ecology, culture (including different systems), improvement, and protection, with a section on cattle (including water buffalo). The broad range of factors that determine different agricultural systems are discussed in DAVID GRIGG, *An Introduction to Agricultural Geography* (1984). Each issue of *The State of Food and Agriculture* (annual), published by the Food and Agriculture Organization of the United Nations (FAO), in addition to world and regional reviews, includes one or more special studies of longer-term issues. The *Yearbook of Agriculture,* published by the U.S. Dept. of Agriculture, each year focusses on a particular theme—*e.g., Farm Management* (1989), *Agriculture and the Environment* (1991), and *New Crops, New Uses, New Markets* (1992). ALFRED H. KREBS, *Agriculture in Our Lives,* 5th ed. (1984), provides an introduction to agricultural business and natural resources. DOUGLAS M. CONSIDINE (ed.), *Foods and Food Production Encyclopedia* (1982), outlines the growth, harvesting, and processing of a large number of foods from plants and animals.

Agricultural economics. THEODORE W. SCHULTZ, *Transforming Traditional Agriculture* (1964, reprinted 1983), has become a classic on the complex problems involved in the modernization of agriculture. The interrelationships between agriculture and the rest of the economy are detailed in ROBERT D. STEVENS and CATHY L. JABARA, *Agricultural Development Principles* (1988), a beginning text; and ISAAC ARNON, *Modernization of Agriculture in Developing Countries: Resources, Potentials, and Problems,* 2nd ed. (1987). *Ceres* (bimonthly), published by the FAO, addresses agriculture and food production in developing countries. R. ALBERT BERRY and WILLIAM R. CLINE, *Agrarian Structure and Productivity in Developing Countries* (1979), establishes a correlation between small farm size and agricultural productivity in developing countries. D. GALE JOHNSON, *World Agriculture in Disarray,* 2nd ed. (1991), analyzes the relationship between domestic agricultural policies and international trade. Various farming systems are examined by B.L. TURNER II and STEPHEN B. BRUSH (eds.), *Comparative Farming Systems* (1987), case studies of 12 major world systems; ZHORES A. MEDVEDEV, *Soviet Agriculture* (1987), a historical treatment; and KARL-EUGEN WÄDEKIN (ed.), *Communist Agriculture: Farming in the Soviet Union and Eastern Europe* (1990), a look at the Communist approach before its abandonment.

Farm buildings. Illustrated texts include JOHN B. WELLER, *Farm Buildings,* 2 vol. (1965–72), a comprehensive technical book; JAMES S. BOYD and VIRGINIA T. BOYD, *Practical Farm Buildings,* 2nd ed. (1979); JAMES H. WHITAKER, *Agricultural Buildings and Structures* (1979); R.J. LYTLE, *Farm Builder's Handbook, with Added Material for Pole Type Industrial Buildings,* 3rd ed. (1978, reissued 1982); and R.W. BRUNSKILL, *Traditional Farm Buildings of Britain,* 2nd ed. (1987). DAVID SAINSBURY, *Animal Health and Housing* (1967), emphasizes physiologic and sanitary aspects. ORGANIZATION FOR ECONOMIC COOPERATION AND DEVELOPMENT, *Capital and Finance in Agriculture* (1970), discusses the national economic impact of farm buildings in many countries.

Farm management. Principles of farm organization, planning, management, and operation are set forth in DONALD D. OSBURN and KENNETH C. SCHNEEBERGER, *Modern Agricultural Management,* 2nd ed. (1983); JOHN E. KADLEC, *Farm Management* (1985); ROBERT A. LUENING, RICHARD M. KLEMME, and WILLIAM P. MORTENSON, *The Farm Management Handbook,* 7th ed. (1991); and WARREN F. LEE *et al., Agricultural Finance,* 8th ed. (1988). Works specifically on agricultural machinery include HARRIS PEARSON SMITH and LAMBERT HENRY WILKES, *Farm Machinery and Equipment,* 6th ed. (1976); ARCHIE A. STONE and HAROLD E. GULVIN, *Machines for Power Farming,* 3rd ed. (1977); DONNELL HUNT, *Farm Power and Machinery Management,* 8th ed. (1983); and CLAUDE CULPIN, *Farm Machinery,* 12th ed. (1992).

Plant cultivation. Overviews are presented by R.H.M. LANGER and G.D. HILL, *Agricultural Plants,* 2nd ed. (1991), a description of the major varieties and their products; JULES JANICK *et al., Plant Science: An Introduction to World Crops,* 3rd ed. (1981); and J.W. PURSEGLOVE, *Tropical Crops: Dicotyledons,* 2 vol. (1968, reissued in 1 vol., 1974), and *Tropical Crops: Monocotyledons,* 2 vol. (1972, reprinted in 1 vol., 1988). GEORGE W. COX and MICHAEL D. ATKINS, *Agricultural Ecology* (1979), analyzes world grain and vegetable production systems, with an emphasis on the influence of weather. GLENN O. SCHWAB *et al., Soil and Water Conservation Engineering,* 4th ed. (1993), is also instructive.

Works focussing on plant breeding include JOHN MILTON POEHLMAN, *Breeding Field Crops,* 3rd ed. (1987); NEAL F. JENSEN, *Plant Breeding Methodology* (1988); and ABRAHAM BLUM, *Plant Breeding for Stress Environments* (1988). K.K. FRAMJI, B.C. GARG, and S.D.L. LUTHRA, *Irrigation and Drainage in the World,* 3rd ed., rev. and enlarged, 3 vol. (1981–83), outlines the development of irrigation in various countries of the world and describes major projects. B.A. STEWART and D.R. NIELSEN (eds.), *Irrigation of Agricultural Crops* (1990), considers both theoretical and practical aspects. GLENN J. HOFFMAN, TERRY A. HOWELL, and KENNETH H. SOLOMON (eds.), *Management of Farm Irrigation Systems* (1990), is a practical handbook. Factors in soil preparation are analyzed by WILLIAM R. GILL and GLEN E. VANDEN BERG, *Soil Dynamics in Tillage and Traction* (1967); MILTON A. SPRAGUE and GLOVER B. TRIPLETT (eds.), *No-Tillage and Surface-Tillage Agriculture* (1986), a review of these alternatives to traditional plowing; RONALD E. PHILLIPS and SHIRLEY H. PHILLIPS (eds.), *No-Tillage Agriculture: Principles and Practices* (1984); and SAMUEL L. TISDALE *et al., Soil Fertility and Fertilizers,* 5th ed. (1993).

Various cropping systems are described in JOHN VANDERMEER, *The Ecology of Intercropping* (1989); and CHARLES A. FRANCIS (ed.), *Multiple Cropping Systems* (1986). HUBERT MARTIN and DAVID WOODCOCK, *The Scientific Principles of Crop Protection,* 7th ed. (1983), focusses on pest control. Regional variations in farming technique are presented by K.G. BRENGLE, *Principles and Practices of Dryland Farming* (1982); HANS RUTHENBERG *et al., Farming Systems in the Tropics,* 3rd ed. (1980); and L.V. CROWDER and H.R. CHHEDA, *Tropical Grassland Husbandry* (1982). JAMES SHOLTO DOUGLAS, *Advanced Guide to Hydroponics,* new ed. (1985); and HOWARD M. RESH, *Hydroponic Food Production,* 4th ed. (1989), treat this specialized technique.

Weather information is available in *Weekly Weather and Crop Bulletin,* published by the U.S. Dept. of Commerce, Weather Bureau. Studies of agricultural meteorology include RUDOLF GEIGER, *The Climate Near the Ground* (1965; originally published in German, 4th ed., 1961), a classic text; JEN-HU CHANG, *Climate and Agriculture* (1968); ROBERT H. SHAW (ed.), *Ground Level Climatology* (1967); and NORMAN J. ROSENBERG, BLAINE L. BLAD, and SHASHI B. VERMA, *Microclimate,* 2nd ed. (1983). DAVID J. BRIGGS and FRANK M. COURTNEY, *Agriculture and the Environment* (1985), describes temperate agricultural practices and systems and their impact on the environment, with examples from Britain. MERVYN L. RICHARDSON, *Chemistry, Agriculture, and the Environment* (1991), focusses on pesticide and fertilizer pollution from both crop and livestock production. Pollution's effect on agriculture is reported in JAMES J. MACKENZIE and MOHAMED T. EL-ASHRY (eds.), *Air Pollution's Toll on Forests and Crops* (1989).

Animal husbandry. Overviews include JAMES BLAKELY and DAVID H. BADE, *The Science of Animal Husbandry,* 5th ed. (1989); JOHN R. CAMPBELL and JOHN F. LASLEY, *The Science of Animals That Serve Humanity,* 3rd ed. (1985); M.E. ENSMINGER, *Animal Science,* 9th ed. (1991); W.J.A. PAYNE, *An Introduction to Animal Husbandry in the Tropics,* 4th ed. (1990); and CLARENCE E. BUNDY, RONALD V. DIGGINS, and VIRGIL W. CHRISTENSEN, *Livestock and Poultry Production,* 5th ed. (1982). Volumes in the *World Animal Science* series discuss, among other topics, animal health, genetics and breeding, feeds, and the production of several of the livestock species addressed below (including buffalo).

The principles and practices of animal breeding are described by ENOS J. PERRY (ed.), *The Artificial Insemination of Farm Animals,* 4th rev. ed. (1968); EVERETT JAMES WARWICK and JAMES EDWARD LEGATES, *Breeding and Improvement of Farm Animals,* 7th ed. (1979); FREDERICK B. HUTT and BENJAMIN A. RASMUSEN, *Animal Genetics,* 2nd ed. (1982); FRANZ PIRCHNER, *Population Genetics in Animal Breeding,* 2nd ed. (1983; originally published in German, 2nd rev. and expanded ed., 1979); and MALCOLM B. WILLIS, *Dalton's Introduction to Practical Animal Breeding,* 3rd ed. (1991). Textbooks and reference works that are useful sources of information on animal nutrition include OSKAR KELLNER, KRAFT DREPPER, and KLAUS ROHR, *Grundzüge der Fütterungslehre,* 16th completely rev. ed. (1984); LEONARD A. MAYNARD *et al., Animal Nutrition,* 7th ed. (1979); ARTHUR E. CULLISON and ROBERT S. LOWREY, *Feeds and Feeding,* 4th ed. (1987); PETER R. CHEEKE, *Applied Animal Nutrition* (1991); and D.C. CHURCH, *Livestock Feeds and Feeding,* 3rd ed. (1991).

Cereal farming. Y. POMERANZ, *Modern Cereal Science and Technology* (1987), discusses common aspects of cereal grains and their products followed by in-depth descriptions of selected cereals. NEAL C. STOSKOPF, *Cereal Grain Crops* (1985), is also useful for an overview. Various grains and their production are investigated in Y. POMERANZ (ed.), *Wheat: Chemistry and Technology,* 3rd ed. (1988); L.T. EVANS and W.J. PEACOCK (eds.), *Wheat Science, Today and Tomorrow* (1981), a collection of essays on current international wheat research; ROBERT W. JUGENHEIMER, *Corn: Improvement, Seed Production, and Uses* (1976, reprinted 1985); D.H. GRIST, *Rice,* 6th ed. (1986); D.E. BRIGGS, *Barley* (1978); and HUGH DOGGETT, *Sorghum,* 2nd ed. (1988).

Vegetable farming. Production techniques for commercial and private vegetable crops are found in *Knott's Handbook for Vegetable Growers,* 3rd ed. by OSCAR A. LORENZ and DONALD N. MAYNARD (1988); IB LIBNER NONNECKE, *Vegetable Production* (1989); MAS YAMAGUCHI, *World Vegetables: Principles, Production, and Nutritive Values* (1983); and MARK J. BASSETT (ed.), *Breeding Vegetable Crops* (1986).

Fruit farming. Fruit culture is presented in NORMAN FRANKLIN CHILDERS, *Modern Fruit Science,* 9th ed. (1983), a well-illustrated book on deciduous orchard and small fruit culture in the United States from planting to marketing, with extensive bibliographies; STEVEN NAGY and PHILIP E. SHAW, *Tropical and Subtropical Fruits: Composition, Properties, and Uses* (1980); J.A. SAMSON, *Tropical Fruits,* 2nd ed. (1986); JAMES S. SHOEMAKER, *Small Fruit Culture,* 5th ed. (1978), an in-depth culture and literature review of all important small fruits; GENE J. GALLETTA and DAVID G. HIMELRICK (eds.), *Small Fruit Crop Management* (1990); JASPER GUY WOODROOF, *Tree Nuts: Production, Processing, Products,* 2nd ed. (1979), a complete book on temperate and tropical nuts of economic importance; and MICHAEL O'BRIEN, BURTON F. CARGILL, and ROBERT B. FRIDLEY (eds.), *Principles & Practices for Harvesting & Handling Fruits & Nuts* (1983).

Livestock farming. The *Animal Agriculture Series,* whose primary author is M.E. ENSMINGER, consists of several works, each devoted to a specific class of farm animal. Examples include M.E. ENSMINGER, *Horses and Horsemanship,* 7th ed. (1999); and M.E. ENSMINGER and R.C. PERRY, *Beef Cattle Science,* 7th ed. (1997). Other volumes in the series treat dairy cattle, sheep, swine, and poultry, and each is copiously illustrated, covering all aspects of production. Other texts addressing the livestock mentioned in this article include A.L. NEUMANN and KEITH S. LUSBY, *Beef Cattle,* 8th ed. (1986); TILDEN WAYNE PERRY, *Beef Cattle Feeding and Nutrition* (1980); J.L. KRIDER, J.H. CONRAD, and W.E. CARROLL, *Swine Production,* 5th ed. (1982); COLIN T. WHITTEMORE, *Pig Production: The Scientific and Practical Principles* (1980); ELWYN R. MILLER, DUANE E. ULLREY, and AUSTIN J. LEWIS (eds.), *Swine Nutrition* (1991); RON PARKER, *The Sheep Book: A Handbook for the Modern Shepherd* (1983); ALLAN FRASER and JOHN T. STAMP, *Sheep Husbandry and Diseases,* 6th ed. rev. by J.M.M. CUNNINGHAM and JOHN T. STAMP (1987); G.J. TOMES, D.E. ROBERTSON, and R.J. LIGHTFOOT, *Sheep Breeding,* 2nd ed. rev. by WILLIAM HARESIGN (1979); DAVID MACKENZIE, *Goat Husbandry,* 4th ed. rev. and edited by JEAN LAING (1980); and DONALD E. ULMER and ELWOOD M. JUERGENSON, *Approved Practices in Raising and Handling Horses* (1974).

Dairy farming. Dairy production and marketing is treated in WILLIAM M. ETGEN, ROBERT E. JAMES, and PAUL M. REAVES, *Dairy Cattle Feeding and Management,* 7th ed. (1987); G.H. SCHMIDT, L.D. VAN VLECK, and M.F. HUTJENS, *Principles of Dairy Science,* 2nd ed. (1988); and DONALD L. BATH *et al., Dairy Cattle: Principles, Practices, Problems, Profits,* 3rd ed. (1985).

Poultry farming. Domestic fowl production is covered by STUART BANKS, *The Complete Handbook of Poultry-Keeping* (1979); RICHARD E. AUSTIC and MALDEN C. NESHEIM, *Poultry Production,* 13th ed. (1990); and HOMER PATRICK and PHILIP J. SCHAIBLE, *Poultry: Feeds and Nutrition,* 2nd ed. (1980).

Beekeeping. Books that concern the life history of the individual bee and the colony, honey and wax production, diseases of bees, flora that provide nectar and pollen, and economics of beekeeping include JOHN E. ECKERT and FRANK R. SHAW, *Beekeeping* (1960); DADANT & SONS (eds.), *The Hive and the Honey Bee,* extensively rev. (1975); and EVA CRANE, *Bees and Beekeeping: Science, Practice, and World Resources* (1990). A.I. ROOT, *The ABC & XYZ of Bee Culture: An Encyclopedia Pertaining to the Scientific and Practical Culture of Honey Bees,* 40th ed. edited by ROGER A. MORSE and KIM FLOTTUM (1990); and ROGER A. MORSE and TED HOOPER (eds.), *The Illustrated Encyclopedia of Beekeeping* (1985), are useful reference works.

Specialty crops. Coverage of the crops discussed in the article is provided by DAME S. HAMBY (ed.), *The American Cotton Handbook,* 3rd ed., 2 vol. (1965–66), a collection of authoritative contributions on subjects ranging from cotton growing to the final finished fabric; JOHN M. MUNRO, *Cotton,* 2nd ed. (1987); B.C. AKEHURST, *Tobacco,* 2nd ed. (1981); and T. EDEN, *Tea,* 3rd ed. (1976). (H.-D.H.W./C.R.H./Ed.)

Feminism

The belief in the social, economic, and political equality of the sexes, feminism originated largely in the West but is manifested worldwide and is represented by various institutions committed to activity on behalf of women's rights and interests.

Throughout most of Western history, women were confined to the domestic sphere, while public life was reserved for men. In medieval Europe, women were denied the right to own property, to study, or to participate in public life. Even as late as the early 20th century, women in the United States, as in Europe, could neither vote nor hold elective office. Women were prevented from conducting business without a male representative, be it father, brother, husband, legal agent, or even son. Married women could not exercise control over their own children without the permission of their husbands. Moreover, women had little or no access to education and were barred from most professions. In some parts of the world, such restrictions on women continue today.

This article is divided into the following sections:

HISTORY OF FEMINISM

The ancient world. There is scant evidence of early organized protest against such circumscribed status. In the 3rd century BC, Roman women filled the Capitoline Hill and blocked every entrance to the Forum when consul Marcus Porcius Cato resisted attempts to repeal laws limiting women's use of expensive goods. "If they are victorious now, what will they not attempt?" Cato cried. "As soon as they begin to be your equals, they will have become your superiors."

That rebellion proved exceptional, however. For most of recorded history, only isolated voices spoke out against the inferior status of women. In late 14th- and early 15th-century France, the first feminist philosopher, Christine de Pisan, challenged prevailing attitudes toward women with a bold call for female education. Her mantle was taken up by Laura Cereta, a Venetian woman who in 1488 published *Epistolae familiares,* a volume of letters dealing with a panoply of women's complaints, from marital oppression to the frivolity of women's attire. Defenders of the status quo painted women as superficial and inherently immoral, while the emerging feminists proclaimed that women would be the intellectual equals of men if they were given equal access to education.

Early debates on the status of women

The so-called "debate about women" did not reach England until the late 16th century. After a series of satiric pieces mocking women was published in 1589, the first feminist pamphleteer in England, writing as Jane Anger, responded with *Jane Anger, Her Protection for Women.* This volley of opinion continued for almost a century, until another English author, Mary Astell, issued a more reasoned rejoinder in *A Serious Proposal to the Ladies* (1697). Astell suggested that women inclined neither toward motherhood nor a religious vocation should set up secular convents where they might live, study, and teach.

Influence of the Enlightenment. The feminist voices of the Renaissance never coalesced into a coherent movement. This happened only with the Enlightenment, when women began to demand that the new reformist rhetoric about liberty, equality, and natural rights be applied to both sexes. For example, the Declaration of the Rights of Man and of the Citizen, which defined French citizenship after the revolution of 1789, pointedly failed to address the legal status of women.

Olympe de Gouges, a noted playwright, published *Déclaration des droits de la femme et de la citoyenne* ("Declaration of the Rights of Woman and of the Citizen," 1791), declaring woman to be not only man's equal but his partner. The following year Mary Wollstonecraft's *A Vindication of the Rights of Woman,* the seminal English-language feminist work, was published in England. She proposed that women and men be given equal opportunities in education, work, and politics. Women, she wrote, are as naturally rational as men. If they are silly, it is only because society trains them to be irrelevant.

The concept of equal opportunity

The Age of Enlightenment turned into an era of political ferment marked by revolutions in France, Germany, and Italy and the rise of the abolition movement. By the mid-19th century, issues surrounding feminism had added to the tumult of social change, with ideas being exchanged across Europe and North America.

In the first feminist article she signed with her own name, Louise Otto, a German, built on the work of Charles Fourier, a French social theorist, quoting his dictum that "by the position which women hold in a land, you can see whether the air of a state is thick with dirty fog or free and clear." And after Parisian feminists began publishing a daily newspaper entitled *La Voix des femmes* ("The Voice of Women") in 1848, Luise Dittmar, a German writer, followed one year later with her journal, *Soziale Reform.*

The suffrage movement. These debates culminated in the first women's rights convention, held in July 1848 in the small town of Seneca Falls, New York. The idea sprang up during a social gathering of Lucretia Mott, a Quaker preacher and veteran social activist, Martha Wright (Mott's sister), Mary Ann McClintock, Jane Hunt, and Elizabeth Cady Stanton, the wife of an abolitionist and the only non-Quaker in the group. Stanton drafted 11 resolutions for the "Declaration of Sentiments" that guided the Seneca Falls Convention. With Frederick Douglass arguing eloquently on their behalf, all 11 resolutions passed, including the most radical demand—the right to the vote.

Although Seneca Falls was followed by women's rights conventions in other states, the interest quickly faded. Concern in the United States turned to the pending Civil War, while, in Europe, the reformism of the 1840s gave way to the repression of the late 1850s. When the feminist movement rebounded, it became focused on a single issue, woman suffrage, a goal that would dominate international feminism for almost 70 years. Stanton and Susan B. Anthony, a temperance activist, formed the National Woman Suffrage Association in 1869. At first, they based their demand for the vote on the Enlightenment principle of natural law, regularly invoking the concept of inalienable rights granted to all Americans by the Declaration of Independence. By 1900, however, the American passion for such principles as equality had been dampened by a flood of Eastern European immigrants and the growth of urban slums. Suffragist leaders, reflecting that shift in attitude, began appealing for the vote not on the principle of justice or on the common humanity of men and women but on racist and nativist grounds. As early as 1894, in a speech, Carrie Chapman Catt declared that the votes of literate, American-born, middle-class women would balance the votes of foreigners: "[C]ut off the vote of the slums and give to woman . . . the ballot."

This elitist inclination widened the divide between feminists and the masses of American women who lived in those slums or spoke with foreign accents. As a result, working-class women—already more concerned with wages, hours, and protective legislation than with either the vote or issues such as women's property rights—threw themselves into the trade union movement rather than the feminists' ranks. In addition, radical feminists challenged the single-minded focus on suffrage as the sine qua non of women's liberation. Emma Goldman, the nation's leading anarchist, mocked the notion that the ballot could secure equality for women, since it hardly accomplished that for the majority of American men. And Charlotte Perkins Gilman, in *Women and Economics* (1898), insisted that women would not be liberated until they were freed from the "domestic mythology" of home and family that kept them dependent on men.

Alice Paul

Ultimately, mainstream feminist leaders such as Stanton failed to secure the vote for women. It took a different kind of radical, Alice Paul, to reignite the woman suffrage movement in the United States by copying English activists. Like the Americans, British suffragists, led by the National Union of Woman Suffrage Societies, had initially approached their struggle with ladylike lobbying. But in 1903, a dissident faction led by Emmeline Pankhurst began a series of boycotts, bombings, and pickets. Their tactics worked, and, in 1918, the British Parliament extended the vote to women householders, householders' wives, and female university graduates over the age of 30.

Following the British lead, Paul's crusaders organized mass demonstrations and confrontations with the police. In 1920, American feminism claimed a major triumph with the passage of the 19th Amendment to the Constitution.

CONTEMPORARY FEMINISM IN THE WEST

The postsuffrage era. Once the crucial goal of suffrage had been achieved, the feminist movement fractured into a dozen splinter groups. The Women's Joint Congressional Committee fought for legislation to promote education and maternal and infant health care; the League of Women Voters organized voter registration and education drives; and the Women's Trade Union League launched a campaign for protective labour legislation for women.

Each of these groups offered some civic contribution, but none was specifically feminist in nature. Filling the vacuum, the National Woman's Party, led by Paul, proposed an Equal Rights Amendment (ERA) that would ban discrimination based on sex while moving women closer to equality. Many feminists, however, were not looking for strict equality; they were fighting for laws that would benefit women. Paul, however, argued that protective legislation—such as laws mandating maximum eight-hour shifts for female workers—actually limited women's opportunities by imposing costly rules on employers, who would then be inclined to hire fewer women.

Questions abounded. What was feminism—a movement to create full equality, or a movement meant to respond to the needs of women? And if the price of equality was the absence of protection, did women really want equality?

This philosophical dispute was confined to relatively rarefied circles. Throughout the United States, as across Europe, Americans believed that women had achieved their liberation. Women were voting, although in small numbers and almost exactly like their male counterparts. Even Suzanne LaFollette, a radical feminist, concluded in 1926 that women's struggle "is very largely won." Before any flaws in that pronouncement could be probed, the nation—and the world—plunged into the Great Depression. Next, World War II largely obliterated feminist activism on any continent. The war did open employment opportunities for women—from working in factories ("Rosie the Riveter" became an American icon) to playing professional baseball—but these doors of opportunity were largely closed after the war, when women routinely lost their jobs to men discharged from military service. This turn of events angered many women, but few were willing to mount any organized protest. By 1960, the percentage of employed female professionals was down compared with figures for 1930.

The "second wave" of feminism. The women's movement of the 1960s and '70s, the so-called "second wave" of feminism, represented a seemingly abrupt break with the tranquil suburban life pictured in American popular culture following World War II. Yet the roots of the new rebellion were buried in the frustrations of college-educated mothers whose discontent impelled their daughters in a new direction. If first-wave feminists were inspired by the abolition movement, their great-granddaughters were swept into feminism by the civil rights movement, the attendant discussion of principles such as equality and justice, and the revolutionary ferment caused by protests against the Vietnam War.

Women's concerns were on President John F. Kennedy's agenda even before this public discussion began. In 1961 he created the President's Commission on the Status of Women and appointed Eleanor Roosevelt to lead it. Its report, issued in 1963, firmly supported preparing women for motherhood. But it also documented a national pattern of employment discrimination, unequal pay, legal inequality, and meagre support services for working women that needed to be corrected through legislative guarantees of equal pay for equal work, equal job opportunities, and expanded child-care services. The Equal Pay Act of 1963 offered the first guarantee, and the Civil Rights Act of 1964 was amended to bar employers from discriminating on the basis of sex. Yet some deemed these measures insufficient in a country where classified advertisements still segregated job openings by sex, where state laws restricted women's access to contraception, or where incidences of rape and domestic violence remained undisclosed.

Renewed activism

Dissension and debate. Mainstream groups such as the National Organization for Women (NOW) launched a campaign for legal equity, while ad hoc groups staged sit-ins and marches for any number of reasons—from assailing college curricula that lacked female authors to promoting the use of the word *Ms.* as a neutral form of address. Health collectives and rape crisis centres were established. Children's books were rewritten to obviate sexual stereotypes. Women's studies departments were founded at colleges and universities. Protective labour laws were overturned. Employers found to have discriminated against female workers were required to compensate with back pay. Excluded from many industries for decades, women began finding jobs as pilots and construction workers, bankers and bus drivers.

Unlike the first wave, second-wave feminism provoked theoretical discussion about the origins of women's oppression, the nature of gender, and the role of the family. Kate Millett's *Sexual Politics* made the best-seller list in 1970, and in it she broadened the term *politics* to include all "power-structured relationships" and posited that the personal was actually political. Shulamith Firestone, a founder of the New York Radical Feminists, published *The Dialectic of Sex* in the same year, insisting that love disadvantaged women by shackling them to men. One year later, Germaine Greer, an Australian living in London, published *The Female Eunuch,* in which she argued that the sexual repression of women cuts them off from the creative energy they need to be independent and self-fulfilled.

Competing ideologies

Any attempt to create a coherent, all-encompassing feminist ideology was doomed. Even the term *liberation* could mean different things to different people. Feminism became a river of competing eddies and currents. "Anarcho-feminists," who found a larger audience in Europe than in the United States, said that women could not be liberated without dismantling such institutions as the family, private property, and state power. Individualist feminists, calling on libertarian principles of minimal government, broke with most other feminists over the issue of turning to government for solutions to women's problems. "Amazon feminists" celebrated the mythical female heroine and advocated liberation through physical strength. And separatist feminists, including many lesbian feminists, preached that women could not possibly liberate themselves without at least a period of separation from men.

Ultimately, three major streams of thought surfaced. The first was liberal, or mainstream, feminism, which focused on pragmatic change at institutional and governmental levels. Its goal was to integrate women into the power structure and to give women equal access to positions men had traditionally dominated. While aiming for strict equality (to be evidenced by an equal number of women and men in positions of power, or an equal amount of money spent on male and female student athletes), mainstream feminism nonetheless supported protective legislation such as special workplace benefits for mothers.

In contrast to this pragmatic approach, radical feminism aimed to reshape society and restructure its institutions, which were seen as inherently patriarchal. Providing the core theory for modern feminism, radicals argued that women's subservient role in society was too closely woven into the social fabric to be unraveled without a revolutionary revamping of society itself. They strove to supplant hierarchical and traditional power relationships they saw as reflecting a male bias.

Finally, cultural or "difference" feminism, the last of the three currents, rejected the notion that men and women are intrinsically the same and celebrated women's differences. Inherent in its message was a critique of mainstream feminism's attempt to enter traditionally male spheres.

The race factor. Like first-wave feminism, the second wave was largely defined and led by the educated middle-class white women who built the movement primarily around their own concerns. This created an ambivalent, if not contentious, relationship with women of other classes and races. Many black women had difficulty seeing white women as their feminist sisters; in the eyes of many African Americans, after all, white women were as much the oppressor as white men. "How relevant are the truths, the experiences, the findings of White women to Black women?" asked Toni Cade Bambara in *The Black Woman: An Anthology* (1970). "I don't know that our priorities are the same, that our concerns and methods are the same." Yet during the first conference of the National Black Feminist Organization, held in New York City in 1973, activists acknowledged that many of the goals central to the mainstream feminist movement—day care, abortion, maternity leave, violence—were critical to African American women as well. On specific issues, then, African American feminists and white feminists built an effective working relationship.

GLOBALIZATION OF FEMINISM

Twentieth-century European and American feminism eventually reached into Asia, Africa, and Latin America. As this happened, women in developed countries, especially intellectuals, were horrified to discover that women in some countries were required to wear veils in public or to endure forced marriage, female infanticide, widow burning, or clitoridectomy. Many Western feminists soon perceived themselves as saviours of Third World women, little realizing that their perceptions of and solutions to social problems were often at odds with the real lives and concerns of women in these regions. In many parts of Africa, for example, the status of women had begun to erode significantly only with the arrival of European colonialism. In those regions, then, the notion that patriarchy was the chief problem—rather than European imperialism—seemed absurd.

Questioning Western views of feminism

The conflicts between women in developed and developing nations have played out most vividly at international conferences. After the 1980 World Conference of the United Nations Decade for Women: Equality, Development and Peace in Copenhagen, women from less-developed nations complained that the veil and female genital surgery had been chosen as conference priorities without consulting the women most concerned. It seemed that their counterparts in the West were not listening to them. During the 1994 International Conference on Population and Development in Cairo, women from the Third World protested outside because they believed the agenda had been hijacked by Europeans and Americans. The protesters had expected to talk about ways that underdevelopment was holding women back. Instead, conference organizers chose to focus on contraception and abortion. "[Third World women] noted that they could not very well worry about other matters when their children were dying from thirst, hunger or war," wrote Azizah al-Hibri, a scholar of Muslim women's rights. "The conference instead centered around reducing thc number of Third World babies in order to preserve thc earth's resources, despite (or is it 'because of') the fact that the First World consumes much of these resources."

Woman and her child during a demonstration, demanding women's rights and the banning of degrading representations of women, held on International Women's Day, March 8, 2001, in New Delhi, India.

The influence of feminism

Still, around the world, women are advancing their interests, although often in fits and starts. Feminism has been derailed in countries such as Afghanistan, where the staunchly reactionary and antifeminist Taliban even banned the education of girls. Elsewhere, feminism has achieved significant gains for women, with the eradication of female genital surgery in many African countries and government efforts to end widow burning in India. More generally, and especially in the West, feminism has influenced every aspect of contemporary life, communication, and debate, from the heightened concern over sexist language to the rise of academic fields such as women's studies and ecofeminism. Sports, divorce laws, sexual mores, organized religion—all have been affected, in many parts of the world, by feminism.

Yet questions remain: How will Western feminism deal with the dissension in its ranks, from women who believe the movement has gone too far and grown too radical? How uniform and successful can feminism be at the global level? Can the problems confronting women in the mountains of Pakistan or the deserts of the Middle East be addressed in isolation, or must such issues be pursued through international forums? Given the unique economic, political, and cultural situations that vary from country to country, the answer to these questions may look quite different in Nairobi than in New York.

BIBLIOGRAPHY. ALICE S. ROSSI (ed.), *The Feminist Papers: From Adams to de Beauvoir* (1973, reprinted 1988), collects the key works of feminism. ROSEMARIE PUTNAM TONG, *Feminist Thought: A More Comprehensive Introduction,* 2nd ed. (1998), provides a comprehensive map of 20th-century feminist thinking. Perspectives from around the world are portrayed in EUGENIA C. DELAMOTTE, NATANIA MEEKER, and JEAN F. O'BARR (eds.), *Women Imagine Change: A Global Anthology of Women's Resistance from 600 B.C.E. to Present* (1997), a representation of women from 30 countries; and MARLENE LEGATES, *Making Waves: A History of Feminism in Western Society* (1996), a comprehensive survey of feminism in Europe, the United States, Canada, and Latin America dating from early Christian times to the present. Texts focusing on feminism in the United States include JANE RENDALL, *The Origins of Modern Feminism: Women in Britain, France, and the United States, 1780–1860* (1984, reissued 1990); and ELEANOR FLEXNER and ELLEN FITZPATRICK, *Century of Struggle: The Woman's Rights Movement in the United States,* enlarged ed. (1996). Questions of class and culture are treated in M. JACQUI ALEXANDER and CHANDRA TALPADE MOHANTY (eds.), *Feminist Genealogies, Colonial Legacies, Democratic Futures* (1997); while UMA NARAYAN, *Dislocating Cultures: Identities, Traditions, and Third-World Feminism* (1997), identifies some misrepresentations of feminist agendas in Third World cultures. KAREN OFFEN, *European Feminisms, 1700–1950: A Political History* (2000), looks at the development of European feminism through the mid-20th century. (E.C.B.)

Ferns and Other Lower Vascular Plants

Vascular plants are those that possess a specialized conducting system for the transport of water, minerals, and food materials, as opposed to the more primitive bryophytes—mosses and liverworts—which lack such a system. They include both the seed plants—angiosperms and gymnosperms, the dominant plants on Earth today—and plants that reproduce by spores—the ferns and other so-called lower vascular plants. The lower vascular plants include the ferns, club mosses, spike mosses, quillworts, horsetails, and whisk ferns. Once considered of the same evolutionary line, these plants were formerly placed in a single group, Pteridophyta, and were known as the ferns and fern allies. Although modern studies have shown that the plants are not in fact related, these terms are still used in discussion of the lower vascular plants.

The pteridophytes represent the oldest of land plants. In their early evolution (during the Devonian and Carboniferous periods, 408 to 286 million years ago), there were many forms that are now extinct. The sphenophytes, for example, were once a large and diverse group of herbs, shrubs, vines, and trees but are now limited to only 15 species of horsetails; the woody lycophytes (club mosses) are entirely gone, leaving only a faint trail in their reduced modern representatives. Much of the fossil fern foliage of the Carboniferous Period is of the uncharacteristic seed ferns, which are the probable antecedents of the flowering plants. Modern ferns represent an explosion of evolution in Cretaceous times (144 to 66.4 million years ago).

The pteridophytes are not an economically important group. Though they are used locally by peoples around the world for medicines and food, their greatest value today is in horticulture (ferns). Their remains, however, provide the bulk of the world's coal beds, and their relatively simple structure and life cycle make them extremely valuable to researchers in understanding the overall picture of plant structure and evolution.

A discussion of all types of plants is found in the article PLANTS. For a discussion of the other types of vascular plants, see GYMNOSPERMS and ANGIOSPERMS. For a discussion of the nonvascular plants, see BRYOPHYTES.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 313, and the *Index.*

The article is divided into the following sections:

General form and function of lower vascular plants

VASCULAR SYSTEM

The conduction system of vascular plants includes the xylem, composed largely of tracheids (tubular cells) in the lower vascular plants and gymnosperms and vessels in angiosperms, for conduction of water and minerals; and the phloem (sieve cells) for conduction of food materials. These vascular tissues are arranged in different patterns in different plant groups and in different parts of the plant.

Structure of the vascular cylinder

The vascular cylinder of a stem or root is called the stele. The simplest and apparently most primitive type of stele is the protostele, in which the xylem is in the centre of the stem, surrounded by a narrow band of phloem. It in turn is bounded by a pericycle of one or two cell layers and a single cell layer of endodermis. The pericycle is generally the layer giving rise to the branches in roots, and the endodermis seems to regulate the flow of water and dissolved substances from the surrounding cortex. More common in fern stems are siphonosteles, having a pith in the centre with the vascular tissue forming a cylinder around it. Where a fern leaf is attached to a stem, a part of the vascular tissue of the stem goes into it (a leaf trace), making a slight gap, filled by parenchyma cells (generalized plant cells), in the vascular cylinder. If the leaves are distant and the stem long and creeping, a single gap will be seen in cross section; if leaves are close together or numerous, the gaps overlap, causing the cylinder to appear in cross section as a ring of disconnected round or elongate bars of vascular tissue.

Generally in pteridophytes, when the young organs mature, no further growth in diameter takes place. In several extinct groups a special ring of cells, the cambium, produced additional xylem to the inside and phloem cells to the outside (secondary growth as opposed to primary growth achieved by apical activity of the stem and root), resulting in increased diameter and a truly woody plant. This is common in many seed plants today, but in the extant pteridophytes only two genera (*Botrychium* and *Isoetes*) show a slight vestige of secondary growth. Even in today's tree ferns (*Cyathea, Dicksonia, Cibotium*), with trunks up to 25 metres (80 feet) tall, the tissues are entirely the result of growth from the stem apex. Their strength is derived not from woody growth in diameter but by strengthening tissues surrounding the vascular bundles and in some cases by a mantle of roots.

CELL TYPES

Cells of the vascular system. The cells of the vascular strands in pteridophytes are mainly tracheids, sieve cells, parenchyma, and endodermal cells. The tracheids, which comprise the xylem, or water-conducting tissue, are normally long, narrow, and attenuated at the tips. Their secondary walls display ladderlike (scalariform) thickenings. The largest tracheids are several centimetres long, but most are much smaller. Vessel cells, which have evolved in several lines of fern evolution and are the principal water-conducting cell type of flowering plants, are modified tracheids in which the end walls have lost their primary membranes, thus providing direct, unimpeded connections for water transport between the cells. Vessels, longitudinal channels composed of linear series of such perforated cells, have been reported from such diverse ferns as waterclover (*Marsilea*) and bracken (*Pteridium*).

The phloem is composed mainly of sieve cells—narrow, elongated units that differ from the tracheids in having persistent protoplasts and nuclei (*i.e.,* they are still alive at functional maturity) and in lacking secondary walls with elaborate pitting. Sieve cells usually display more or less distinguishable sievelike areas, through which, presumably, organic foods pass in their travels through the stem and other plant organs. There are various arrangements of xylem and phloem, but usually a single strand composed of both is surrounded by parenchyma cells, the pericycle (a thin zone of living cells just within the endodermis), and an outer layer of cells with specialized walls, the endodermis. Endodermal cells in young stems are provided with special strips of secondary wall material known as Casparian strips on their radial walls (*i.e.,* on all the cell walls except the two that face toward the stem axis and the stem surface). As the stems age, however, there is a tendency for the endodermal cells to become thick-walled around the entire circumference.

Endodermal cells

Other cells. The pith is made up of parenchyma cells as a rule, but, in some fern genera, scattered tracheid-like cells are found as well. The cells of pteridophyte stems differ from those of many seed plants in lacking collenchyma (modified parenchyma cells with expanded primary walls) and true stone cells. Latex-producing cells in lower vascular plants are rare.

ROOTS

Taproots are unknown in lower vascular plants. All pteridophyte roots are referred to as adventitious, in the sense that they arise at points along the stem. In internal structure, the roots are generally regarded as being much less diverse than the stems. They are protostelic, lacking pith and gaps, and they grow from one or more apical initials (cells that divide to produce all the cells and tissues of an organ), producing a root cap outwardly and the permanent tissues of the root inwardly. They entirely lack secondary growth (continued growth in thickness).

The surface cells of the epidermis produce root hairs near the root apex. These cells are generally thin-walled, in contrast to the cells of the cortex, lying below the surface, which ultimately may become very thick-walled. The root hairs have fundamental importance in absorption of water and nutrients and in attachment of the plant to the soil or other growing surface. The endodermis of the root is well marked, and Casparian strips are present, as in the stem. There is also a tendency for the endodermis in older parts of the roots to become thick-walled and hardened (sclerified).

The production and development of xylem tissue in the steles of most pteridophyte roots is diarch; that is, the first matured xylem appears along two lines at the outer periphery of the xylem strand. The xylem is surrounded by phloem, and the branch roots arise from the pericycle.

LEAVES

Stem appendages known as leaves take various forms that evolved independently in different groups of lower vascular plants. The simplest are scalelike emergences, or enations, that are not served by vascular tissue (*i.e.,* they have no veins), found in some extinct groups and in modern whisk ferns (*Psilotum*). The lycophytes have scalelike, needlelike, or awl-shaped "microphylls" with a single, unbranched vein. The sphenophytes have "sphenophylls"—scalelike leaves with a single vein in the modern *Equisetum* or wedge-shaped leaves with a dichotomously forking vein system in many of the fossil forms. These leaf forms are all so simple that the vascular connection with the stem stele does not affect the stele configuration and causes no leaf gap. On the other hand, the complex leaves of ferns (pteridophylls, or megaphylls) probably evolved from a branching stem system and affect the stele by drawing out enough vascular tissue to cause a leaf gap.

REPRODUCTION

The life cycle of pteridophytes exhibits an alternation of generations between gametophytes and sporophytes. The gametophytes are sexual plants producing eggs or sperm or both, and the sporophytes are asexual plants producing spores that are capable of producing new gametophytes. The sporophyte of lower vascular plants, in contrast to that of mosses and liverworts, is obviously the dominant generation. Unlike seed plants, which also have dominant sporophytes, pteridophytes reproduce not by forming seeds but by producing spores—minute single cells covered by a protective wall and readily carried by the wind. The life cycle of these plants is referred to as pteridophytic, or fernlike, as opposed to spermatophytic (seed-plant-like).

Sporophytes

The plant begins life as a spore. The germinating spore grows into a small gametophyte, or prothallium, usually only 0.3 to 1 centimetre (0.2 to 0.4 inch) long or broad, bearing rhizoids (hairlike structures for water and mineral absorption and attachment to the soil). Gametophytes may be green, occurring on the soil surface, or colourless, occurring under the soil (usually saprophytically, with the aid of a mycorrhizal fungus). Sex organs, called antheridia and archegonia, produce sperm and eggs, respectively. The sperm require water in which to swim to the egg for fertilization. The fertilized egg, or zygote, contains one set of chromosomes from each of the two sex cells. The zygote then divides, developing into an embryo, which in turn develops the first leaf, root, and stem apex. The resulting plant, the sporophyte, is the characteristic plant that is normally seen. At maturity, sporangia (spore cases) are produced; in them the spore mother cells divide by a special nuclear division, meiosis, in which the chromosome number is reduced to a single set for each of four resulting spores.

In most pteridophytes all the spores of each plant are alike, and the plant is said to be homosporous. A few groups (the lycophytes *Selaginella* and *Isoetes* and, among the ferns, the water-fern families Marsileaceae, Salviniaceae, and Azollaceae) are heterosporous, forming two types of spores. These plants have two kinds of sporangia, one producing a few large megaspores (holding food reserves for the early development of the embryo) and the other producing many small microspores. The microspore divides to form a reduced gametophyte, merely a jacket of cells and a few sperm cells; the megaspore divides to form a mass of tissue and archegonia, each enclosing an egg.

The life cycle of the lower vascular plants is basically the same as that of seed plants. The main difference is that in seed plants the new young sporophyte (embryo) is kept within a structure (seed) on the parent plant before dispersal and perhaps a resting stage, whereas in lower vascular plants dispersal and resting take place in the spore before the embryo is formed.

Ferns

Ferns are plants belonging to the vascular plant division Filicophyta, having leaves with branching vein systems and the young leaves usually unrolling from a tight fiddlehead, or crosier. The number of fern species is usually placed at approximately 12,000, but estimates range from as low as 9,000 to as high as 15,000, the number varying because certain groups are as yet poorly studied and new species are still being found in unexplored tropical areas. The ferns constitute an ancient division of vascular plants, some of them as old as the Carboniferous Period (beginning 360 million years ago) and perhaps older. Their type of life cycle, dependent upon spores for dispersal, long preceded the seed-plant life cycle.

GENERAL FEATURES

Diversity of fern types

Size range and habitat. The ferns are extremely diverse in habitat, form, and reproductive methods. In size alone they range from minute filmy plants only 2 to 3 millimetres (0.08 to 0.12 inch) tall to huge tree ferns 10 to 25 metres (30 to 80 feet) in height. Some are twining vines; others float on the surface of ponds. The majority of ferns inhabit warm, damp areas of the Earth. Growing profusely in tropical areas, ferns diminish in number with increasingly higher latitudes and decreasing supplies of moisture. Few are found in dry, cold places.

Some ferns play a role in ecological succession, growing from the crevices of bare rock exposures and in open bogs and marshes prior to the advent of forest vegetation. The best-known fern genus over much of the world, *Pteridium,* the bracken, is characteristically found in old fields, where in most places it is ultimately succeeded by woody vegetation.

Distribution and abundance. Geographically, ferns are most abundant in the tropics. Arctic and Antarctic regions possess few species. On the other hand, a small, tropical country such as Costa Rica may have more than 900 species of ferns—more than twice as many as are found in all of North America north of Mexico. The finest display of fern diversity is seen in the tropical rain forests, where in only a few acres more than 100 species may be encountered, some of which may constitute a dominant element of the vegetation. Also, many of the species grow as epiphytes upon the trunks and branches of trees. A number of families are almost exclusively tropical (*e.g.,* Marattiaceae, Gleicheniaceae, Grammitidaceae, Schizaeaceae, Cyatheaceae, Blechnaceae, Davalliaceae). Most of the other families occur in both the tropics and the temperate zones. Only certain genera are primarily temperate and Arctic (*e.g., Athyrium, Cystopteris, Dryopteris, Polystichum*), and even these tend to extend into the tropics, being found at high elevations on mountain ranges and volcanoes.

Ferns as weeds are uncommon, although a few occur. The most notorious is the bracken (*Pteridium*), which spreads quickly by its underground, ropelike rhizome, rapidly invading abandoned fields and pastures in both temperate and tropical regions. One species of water spangles (*Salvinia auriculata*) became a major pest in India, blocking irrigation ditches and rice paddies. Another species (*S. molesta*) within three years covered 520 square kilometres (200 square miles) of the artificial Lake Kariba in southern Africa, cutting off light and oxygen and thus killing other plant life and fish. Some fern species have been introduced into tropical or subtropical areas (*e.g.,* southern Florida and Hawaii) and in some cases have become naturalized and have spread into the native forest. Examples include the giant polypody (*Microsorium scolopendrium*), climbing ferns (*Lygodium japonicum* and *L. microphyllum*), green cliff brake (*Pellaea viridis*), silver fern (*Pityrogramma calomelanos*), Japanese holly fern (*Cyrtomium falcatum*), rosy maidenhair (*Adiantum hispidulum*), Cretan brake (*Pteris cretica*), and ladder brake (*P. vittata*). Two Old World species (*Thelypteris dentata* and *T. torresiana*) were introduced into tropical America beginning about 1930 and now are among the most common species even in some remote areas.

Because of their ability to disperse by spores and their capacity to produce both sex organs on the same gametophyte and thus to self-fertilize, it would seem logical to assume that the ferns possess higher powers of long-distance dispersal and establishment than do seed plants. This conclusion tends to be supported by the fact that remote disjunctions—separated growing regions—in range are frequent among ferns. There are interisland and intercontinental disjunctions, east and west, as well as wide north-south disjunctions including species found in the Northern and Southern hemispheres that skip the tropics. Some disjunctions seem to follow the pattern of prevailing winds; the main centre of distribution of a species often may lead to downwind groups consisting of one or a few small populations sometimes hundreds or thousands of miles away. Examples of species exhibiting west-to-east transcontinental disjunctions in North America are Wright's cliff brake (*Pellaea wrightiana*), mountain holly fern (*Polystichum scopulinum*), and forked spleenwort (*Asplenium septentrionale*); all of these ferns are well known in the western United States, and they exist as tiny populations in the mountains of the eastern states as well. Some species are disjunct between continents, such as between New Zealand and South America (*Blechnum penna-marina* and *Hypolepis rugosula*) or South Africa and Australia and New Zealand (*Todea barbara*). Some disjunct patterns, such as similar plants growing in Asia and in eastern North America, are not the result of long-range dispersal but rather are the remnants of an ancient continuous flora, the intervening areas having been changed over time.

Disjunctions in range

Importance to humans. As a group of plants, ferns are not of great economic value. Many different species have been used as a minor food source and for medicine in various parts of the world. Edible fern crosiers (young leaves with coiled, hook-shaped tips) are popular in some areas. The ostrich fern (*Matteuccia*) of northeastern North America is frequently eaten, apparently with no ill effect, but the two ferns most commonly consumed in East Asia (*Osmunda* and *Pteridium*) have been shown to be strongly carcinogenic. The minute, aquatic mosquito fern (*Azolla*) has become a valuable plant, especially in Southeast Asia; a blue-green alga (*Anabaena azollae*) is always found in pockets on the leaves of *Azolla* and helps convert nitrogen to a form usable by other plants, thus greatly increasing the productivity of rice paddies where the fern occurs. The greatest economic value of ferns has been in horticulture, with large nurseries supplying millions of plants annually for both indoor decoration and outdoor gardens and landscaping.

A major value of ferns is in biological research, for they have retained a primitive life cycle involving two separate and more or less independent generations, or growth phases, the plants of which are wholly different in many respects.

NATURAL HISTORY

Life cycle. The typical fern, a sporophyte, consists of stem, leaf, and root; it produces spores; and its cells each have two sets of chromosomes, one set from the egg and one from the sperm. The sporophyte of most ferns is perennial (it lives for several years) and reproduces vegetatively by branching of the rootlike underground stem, or rhizome, often forming large, genetically uniform colonies, or clones. A few ferns propagate by root proliferations, and some, especially in the wet tropics, reproduce by leaf proliferations.

The spores are haploid; that is, they have one set of chromosomes. They are produced in specialized organs—the spore cases, or sporangia—on the fern leaves (sporophylls). Once released, the spores are carried by wind currents, and a small percentage of them fall in appropriate germination sites to form the sexual plants, or gametophytes. In ferns the gametophytes are commonly referred to as prothallia,

Spore dispersal

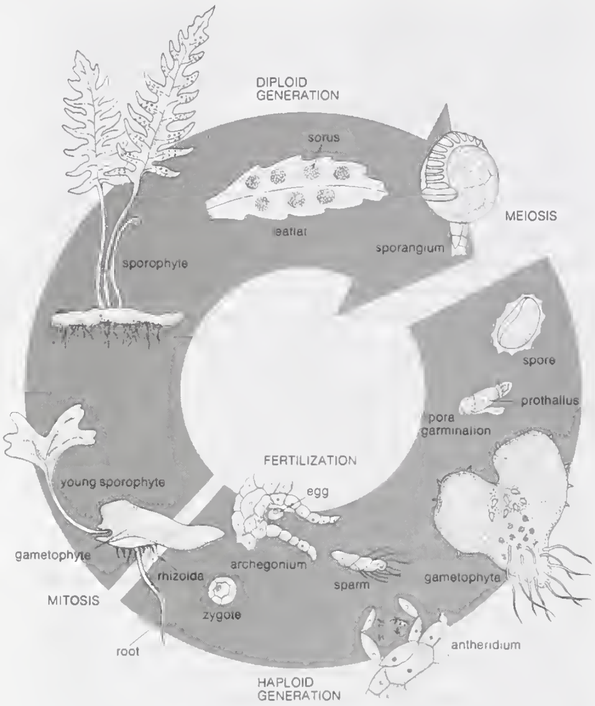

Figure 1: Fern life cycle.
Drawing by M. Pahl

and they are best known to biologists as laboratory objects in artificial culture. They are rarely observed in nature without arduous searching, and the gametophyte stage of the majority of fern species has never been seen in the wild.

The prothallia are tiny—usually less than 8 millimetres (0.3 inch) long—and kidney-shaped in the majority of species. They grow only until the new sporophyte is formed by fertilization; then they wither and die. The process of fertilization is accomplished by sperm and eggs produced upon the same or different gametophytes, and both the fertilized egg (zygote) and the resultant embryo are held within the tissues of the prothallium until the embryo grows out as an independent plant.

Ecology. Ecologically, the ferns are mostly plants of shaded, damp forests of both temperate and tropical zones. Some fern species grow equally well on soil and upon rocks; others are confined strictly to rocky habitats, where they occur in fissures and crevices of cliff faces, boulders, and taluses. Acidic rocks such as granites, sandstones, and quartzites are associated with characteristic fern species different from those of alkaline rocks such as calcites and dolomites. A few species appear to be confined to serpentine and related rocks. In the tropics as many as two-thirds of the ferns of an area may grow as epiphytes on the shaded lower trunks and branches or in the crowns of trees. A few so-called epiphytic ferns are actually climbers that originate upon the ground and grow up tree trunks. In these the lower leaves (bathyphylls) are usually sterile and often different in form from those at the higher levels (acrophylls), which are entirely or partly fertile in that they bear sporangia over their surfaces.

Both epipetric (growing on rocks) and epiphytic ferns may show structural adaptations to dry habitats similar to those of desert plants. These adaptive features include such specializations as hard tissues and thick texture; the surface cells, or epidermis, may be provided with a very thick cuticle (a waxy layer); and abundant hairs or scales may be found on the leaf and stem surfaces. Terrestrial ferns, growing on the ground, may also possess such modifications, especially those that grow in salt marshes (*e.g.,* leather ferns, *Acrostichum*) and open, fully exposed prairies and savannas (*e.g.,* bracken, *Pteridium;* lip ferns, *Cheilanthes;* brakes, *Pteris*).

Ferns that grow in the open are often referred to as sun ferns (*e.g., Gleichenia*) and do not (at least as mature plants) require shade, as do most ferns. Water ferns—waterclovers (*Marsilea*), water spangles (*Salvinia*), and mosquito ferns (*Azolla*)—surprisingly are very commonly inhabitants of dry regions. They appear only after rains, however, and their growth and life cycles are accomplished rapidly, probably as an adaptation to the need for making quick use of water. These ferns have two types of spores that essentially lack the vegetative phase of other ferns; they simply produce sex organs and sperm and eggs rapidly, utilizing food in the spores. Many inhabitants of dry rock cliffs, especially in the maidenhair family, Adiantaceae, have developed a modified type of life cycle known as apogamy, in which fertilization is bypassed. This life cycle is also believed to foster quick reproduction in connection with brief damp periods; the gametophytes grow quickly, with buds developing directly into sporophytes; thus, free water is not required for swimming sperm.

Apogamous reproduction

Parasites and animals that feed upon ferns do not seem to be numerous, although the information available is not complete. Fungi infect ferns, some of them producing soruslike (*i.e.,* resembling the sorus, the sporangium cluster of ferns) dark bodies, or sclerotia. Snails and slugs commonly attack young, uncurling fronds (leaves) of some species, and various beetles have been observed to graze upon ferns. Partially eaten or insect-damaged fronds are not commonly observed in most fern species, however, which suggests that they may contain repulsive substances that ward off grazers. Many ferns have chemical compounds similar or identical to molting hormones of insects, and these may play a role in protecting the plants from major insect damage.

Although the sporophyte is long-lived, the fern gametophyte is usually ephemeral. It develops in a microenvironment characterized by little competition from other plants (including even mosses and algae); exposed humus, decomposing plant materials, or fresh mineral surfaces; deep to moderate shade; and a humid atmosphere. Even ferns whose sporophytes tolerate sun and drought tend to have these requirements for their gametophytes. On rocks, for example, the gametophytes form in protected crevices in which light is minimal and moisture maximal. Because of their requirements for exposed soil, development of fern gametophytes is promoted by damage to mature vegetation, such as fallen trees in the forest, flooding, and deep erosion. Prothallia are observed in nature most commonly upon shaded soil banks in forests and along streams and upon rotting logs.

As the bulk of reproduction of ferns is probably vegetative, taking place in the sporophytic stage, the presence of a large stand of a particular kind of fern results not so much from sexual reproduction by gametophytes as from clone formation by rhizomes and in some cases by root or leaf proliferations. In fact, vegetative reproduction probably accounts for the bulk of fern plants in the world; the sexual cycle, including spores and independent gametophytes, is probably important primarily in invading new

Drawing by M. Pahl

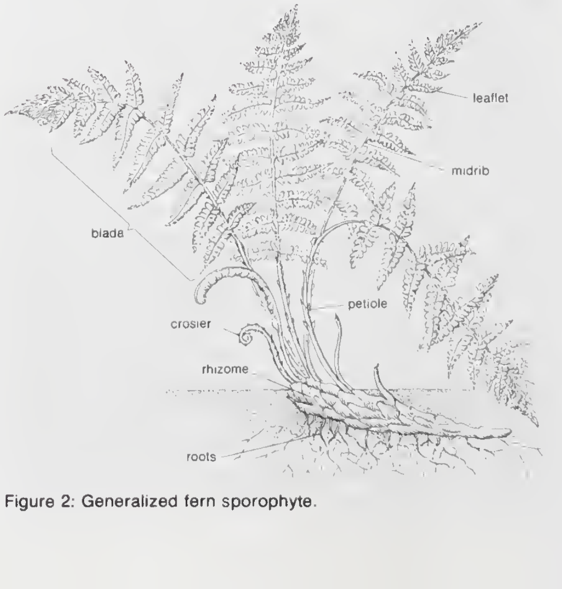

Figure 2: Generalized fern sporophyte.

habitats, extending the plant's geographic range, and creating ever-so-slight variations through rearrangement of the genetic material during meiotic cell division immediately preceding spore production.

FORM AND FUNCTION

Spore. The fern spore—a single living cell, usually protected by a thick wall—is the main source of population dispersal, being readily carried by wind. Ferns display a wide diversity of spore types in terms of shape, wall structure, and sexuality, and these types prove to have great value in determining taxonomic relationships. The full functional significance of the different types, except on the grossest scale, is not yet fully understood; for example, the minute differences in sculpturing of the outer wall surface do not, in the present state of knowledge, appear to have functional significance.

The tetrahedral spore

Shape. The basic spore shape among ferns is tetrahedral; the proximal face (the one facing inward during the tetrad, or four-cell, stage following reduction division, or meiosis) is made up of three sloping planes, and the distal, or outer, face consists of a single rounded surface. The tetrahedral structure is commonly obscured in so-called globose spores, the walls of which are thin and soft. Typically, the wall is composed of exospore (outer spore layer) only, there being no additional jacket, or perispore. The wall may be either unsculptured and smooth or provided with a variety of sculptured patterns. The tetrahedral spore is formed by simultaneous division of the products of the spore mother cell.

In contrast, the bilateral spore type of many fern species is formed by successive cell divisions of the spore mother cell. Where the tetrahedral spore possesses a triradiate scar on the proximal face—corresponding to its contact with three other spores in the tetrad—the bilateral spore has only a narrow, linear scar running parallel to the long axis. Most bilateral spores in ferns are bean-shaped and jacketed by a perisporial layer, a distinctive covering of the outer wall.

Size. Most ferns are homosporous, each plant having spores of one shape and size, usually 30 to 50 micrometres in length or diameter, although some reach more than 100 micrometres. A few fern families, however, have dimorphic spores, small ones (microspores) and large ones (megaspores). The gametophytes of ferns with dimorphic spores are endosporous; that is, they do not emerge in germination and fail to grow beyond the confines of the spore walls. Photosynthesis is essentially lacking, the food being stored in the spore. The microspores produce sperm in antheridia, and the megaspores produce eggs in archegonia. The vegetative phase of the gametophyte in these forms has been practically eliminated, and the developing embryo in the megaspore lives on stored food materials. The differentiation between male and female gametophytes ensures cross-fertilization. This set of conditions, known only in the families Marsileaceae, Azollaceae, and Salviniaceae, is called heterospory.

Wall. Spore walls may be thick or thin. Thick-walled spores are capable of surviving for a number of years, in some cases up to several decades. Sporocarps (masses of sporangia) of waterclover (*Marsilea*) 100 years old have been successfully germinated. Most natural germination of fern spores (except for water ferns) occurs on exposed damp surfaces of rock, soil, or dead plant materials.

A number of fern genera (*e.g.*, *Osmunda, Grammitis, Hymenophyllum, Trichomanes, Matteuccia*) possess thin-walled spores. In practically all known examples, such thin-walled spores are also green-pigmented, being provided with chloroplasts. Such spores are common among rain forest genera; they are often short-lived and require a short time for germination. Spores of *Hymenophyllum, Trichomanes,* and *Grammitis* remain viable only a few days, those of *Osmunda* a few months.

Growth of the gametophyte

Gametophyte. When the spore wall cracks under appropriate moist conditions, the fern gametophyte is formed. Emerging from the spore at the time of germination are a nongreen rhizoid (rootlike organ), which attaches the plant to the growing surface, and a green single cell—the mother cell that gives rise to the rest of the gametophyte. At first, in most homosporous ferns, growth is in the form of a single filament, and it may continue in this fashion if lighting conditions are weak. If lighting is optimal, however, the gametophyte becomes a two-dimensional sheet of cells and later a layered, three-dimensional structure. The apical cell, which initiates growth, is soon replaced by a growth zone, or meristem, which, as a result of the directions of cell division and enlargement, comes to lie in an apical notch in the gametophyte, surrounded on either side by the prothallial wings—flat, platelike protrusions, one cell thick. The average size of the gametophyte at the time of fertilization is approximately 2 to 8 millimetres (0.08 to 0.32 inch) long and up to 8 millimetres wide.

Specialized forms. From a basic type of gametophyte, somewhat like that just described, a number of highly specialized forms have evolved that are characteristic of certain genera. Ribbonlike gametophytes are known especially among tropical rain forest ferns such as *Vittaria, Grammitis,* and *Hymenophyllum* and are usually irregularly and extensively branched, forming large masses of intertwining ribbons. Some of these are actually more abundant than their corresponding sporophytes in certain localities (*e.g.*, the Appalachian Mountains, where "pure cultures" of gametophytes totally lacking sporophytes have commonly been found). Filamentous (threadlike) gametophytes are known in the genera *Trichomanes* (Hymenophyllaceae) and *Schizaea* (Schizaeaceae).

Tuberlike gametophytes occur in several groups—*e.g.*, the families Ophioglossaceae (all members), Schizaeaceae (*Actinostachys*), and Stromatopteridaceae (*Stromatopteris*). All are nongreen underground plants that have close associations with fungi and are therefore assumed to be saprophytic (*i.e.*, dependent for nutrition upon rotting organic material in the soil). They commonly occur 5 to 10 centimetres (2 to 4 inches) deep in the ground.

In heterosporous ferns the endosporous gametophytes are

Drawing by M Pahl

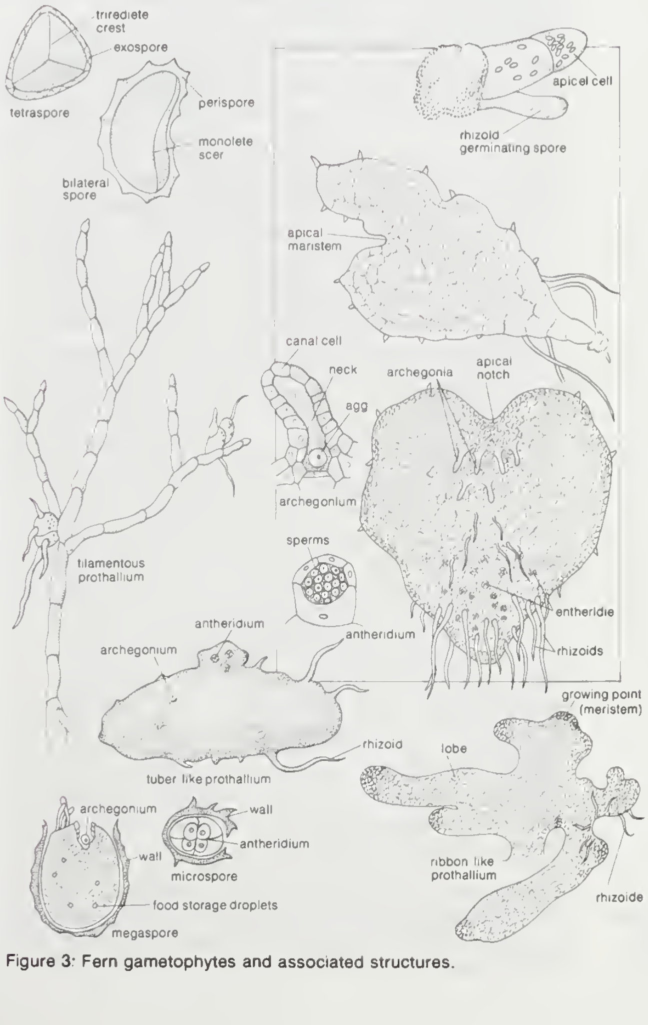

Figure 3: Fern gametophytes and associated structures.

much reduced. The male gametophyte in the microspore is made up of the equivalent of one antheridium and its complement of sperm. The female gametophyte, although considerably larger in size, is equally reduced in a morphological sense, the greater space within the megaspore being filled by stored nutritive materials and tissues formed around the base of the female sex organs.

Vegetative reproduction. Vegetative propagation of some photosynthetic fern gametophytes is accomplished by continued growth and fragmentation, but this does not spread the gametophyte very far. Some ferns (*Vittaria, Grammitis,* and the family Hymenophyllaceae) produce specialized filaments, or gemmae, that break off and are carried away by water droplets, wind, or possibly crickets to initiate new colonies.

Structure of the archegonium

Sexual reproduction. The sex organs of ferns are of two types. The sperm-producing organ, the antheridium, consists of a jacket of sterile cells with sperm-producing cells inside. Antheridia may be sunken (as in the families Ophioglossaceae and Marattiaceae) or protruding. They vary in size from those with hundreds of sperm to those with only 12 or so. The egg-producing organ, the archegonium, contains one gamete (sex cell), which is always located in the lower, more or less dilated portion of the archegonium, the venter. The upper part of the archegonium, the neck, consists of four rows of cells containing central neck cells. The uppermost of the neck cells are the neck canal cells; the lowest cell is the ventral canal cell, which is situated just above the egg.

Fertilization is attained by the ejection of sperm from antheridia. The sperm swim through free water toward simple organic acids released at the opening of the archegonium, the neck of which spreads apart at the apex, permitting the neck cells to be extruded and the sperm to swim in and penetrate the egg. The sperm are made up almost entirely of nuclear material, but their surface is provided with spiral bands of cilia—hairlike organs that effect locomotion. When the egg is fertilized, the base of the neck closes, and the embryo develops within the expanding venter.

Embryo. Within the archegonial venter the zygote undergoes characteristic cell divisions to form the embryo, which remains encapsulated in the gametophyte until it breaks out and becomes an independent plant. The pattern of development in most ferns is a distinctive one, and indeed only in the classes Ophioglossopsida and Marattiopsida—in the *Botrychium* subgenus *Sceptridium* and in all species of the family Marattiaceae thus far studied—are found conditions of embryonic development resembling those of seed plants. Here the first division of the zygote is transverse. The inner cell grows inward, producing the stem and first leaf, and the outer cell divides to form a foot, a mass of tissue that exists as part of the embryo and disappears when its function, presumably absorption, is completed. The root appears later within the stem and grows outward. In all other known ferns the zygote divides neatly into four quadrants, the first division approximately parallel to the long axis of the archegonium and the following division at right angles. This results in initial cells that give rise to four organs: the outer forward cell (*i.e.,* toward the growing apex of the gametophyte and the neck of the archegonium) becomes the first leaf, the inner forward cell the stem apex, the outer back cell the first root, and the inner back cell the foot. Thus, the majority of ferns tend to have a precise arrangement of their organs and the divisions that produce them in the embryo.

The young sporophytes of ferns remain attached to the gametophytes for varying lengths of time, absorbing nutrients from the gametophyte through the foot. Once the sporophyte has developed independent existence and the root has penetrated the soil, the gametophyte soon shrivels.

Ant chambers in fern stems

Stem. Fern stems vary from the tall, narrow trunks of certain tree ferns that reach 25 metres (80 feet) tall down to creeping rootstocks, or rhizomes. Rhizomes are the most common stem form. The majority of them grow horizontally upon or just beneath the surface of the soil. Some stems are so narrow as to be threadlike, as in many tropical epiphytic ferns. A few ferns in different parts of the world have evolved radically specialized stems containing chambers in which ants take up residence; the role of the ants in the lives of these ferns is unknown, but it may be for protection against other insects. Vinelike ferns are common, but shrubby ferns are extremely rare.

Figure 4: Stem structures in ferns.
Drawing by M. Pahl

Stem growth is initiated by one to several large apical cells. These are usually well protected by various types of hairs or scales and by the overarching embryonic leaves. Leaves and leaf bases play a major role in the protection of fern stems, and many stems are said to have a leaf armour. Such stems are densely covered with old, sclerified leaf bases, which increase the apparent size of the stem many times. The old leaf bases may serve as protection or as food storage organs. In most species the stems are indeterminate in growth and thus can theoretically continue to grow indefinitely. Annuals—short-lived species that complete development, shed spores, and die in a single growing season—are exceptional; only one or two examples are known.

Surface structure. Whether covered with leaf armour or not, the surface of the fern stem is protected by an epidermis, or "skin," a single layer of epidermal cells, which are more or less flat cells with thick outer walls. Most fern stems also are covered with a protective indument, consisting of hairs or scales; these are so distinctive that they are valuable in identification and classification. The indument includes such diverse types of epidermal emergences as simple glands (unbranched, one- to several-celled hairs with a headlike cluster of secretory terminal cells); simple (unbranched), nonglandular hairs; dendroid hairs (branching filaments); and scales (flat cell plates) of many patterns. Scales (also known as paleae) are defined as a cell plate two or more cell rows wide, at least at the base, whereas hairs generally have a single row of cells. Transitional states are also known.

Cortex. The cortex is the region outside the vascular cylinder but below the surface of the stem. It is composed mostly of storage parenchyma cells (a relatively generalized cell type). Rooting animals, such as pigs, occasionally dig up fern rhizomes for the starchy materials contained in them. There is a strong tendency for the outermost cortical cells to become darkly pigmented and thick-walled.

Types of steles

Vascular tissues. The steles—cylinders of vascular tissues in the centres of fern stems—exhibit somewhat diverse patterns. Most common ferns possess a "dictyostele," consisting of vascular strands interconnected in such a manner that, in any given cross section of stem, several distinct bundles can be observed. These are separated by regions filled with parenchyma cells known as leaf gaps. There are, however, numerous "siphonostelic" ferns, in which the gaps do not overlap and a given section shows only one gap, and some "protostelic" ferns, in which no gaps at all are formed. Complex stelar patterns are known in some species, as in the common bracken fern (*Pteridium*), which has a polycyclic dictyostele, one in which one stele occurs within another stele; large strands of fibrelike cells running between them form mechanically specialized hard tissue, or sclerenchyma.

Root. Fern roots are generally thin and wiry, although some are fleshy and either slender (in the Ophioglossaceae) or as much as 13 millimetres (0.5 inch) in diameter (*e.g., Acrostichum, Marattia*). The relation of the roots to the stems is a valuable identification tool. For example, in certain tree ferns (*e.g., Cyathea, Cibotium*) and in the royal ferns (*Osmunda*) the entire stem surface is covered by masses of roots. If large enough, the dead tangles of tree fern roots can be cut with a saw into various shapes suitable for attaching epiphytic greenhouse plants, and pieces of such root masses have proved to be useful in horticulture for cultivating orchids and bromeliads. Because of the massive destruction of tree ferns for this purpose, the importation of tree fern logs into many countries is now prohibited. Certain tropical ferns have elaborately hairy roots whose surfaces are covered with locks of silky golden or brown root hairs.

Leaf. *Shapes.* The leaf plan in practically all ferns is pinnate—that is, featherlike with a central axis and smaller side branches—and this is considered to be the primitive condition because of its widespread occurrence. From this basic type there has evolved a broad diversity of forms. Some ferns have palmate leaves (with veins or leaflets radiating from one point), and some, such as the staghorn ferns, have secondarily evolved falsely dichotomous leaves. In some genera (*Lygodium, Salpichlaena*) the main leaf axis (rachis) twines about on shrubs and small trees, sometimes reaching 20 metres (65 feet) in length.

Whether a given leaf is divided into segments (compound) or is undivided (simple) is of considerable value in identification of similar fern species. The difference between divided and undivided leaves is not a profound one, however, and closely related species commonly differ from one another in this respect.

Variations in leaf divisions

The extent of division in fern leaves, or fronds, ranges from that in which the leaf margins are merely so deeply lobed as to have narrow-based segments to that of having obviously stalked leaflets, or pinnae. The pinnae themselves may also be lobed or truly divided with stalked segments as well; and the resulting segments, the pinnules, may also be lobed or divided. Depending on the degree of cutting, fronds are described as simple, once divided, twice divided, thrice divided, and so on. Some ferns are known in which the fronds are five times compound, making them exceedingly delicate, with segments so small as to be almost hairlike.

Venation. Generally, the patterns of the leaf veins, or vascular bundles (which can be seen readily by holding the specimen up to a strong light), are pinnate and the veins are free; that is, they all diverge and never coalesce, either along their sides or at the ends. Nevertheless, there are numerous fern groups in which netted, or reticulate, venation is found. These have vein patterns like those of other ferns for the most part, except that various systems of networks and areolae (areas enclosed within loops of veins) have developed between the major, pinnately arranged veins. There are many reticulate patterns known. One of the more striking is that in which each loop or areola contains one or more free included veinlets, as seen in various members of the family Polypodiaceae. Another is the herringbone pattern, believed to result from an evolutionary concrescence (growing together) of pinnae, as shown by certain tree ferns (*Cyathea*), lady ferns (*Athyrium*), and marsh ferns (*Thelypteris*).

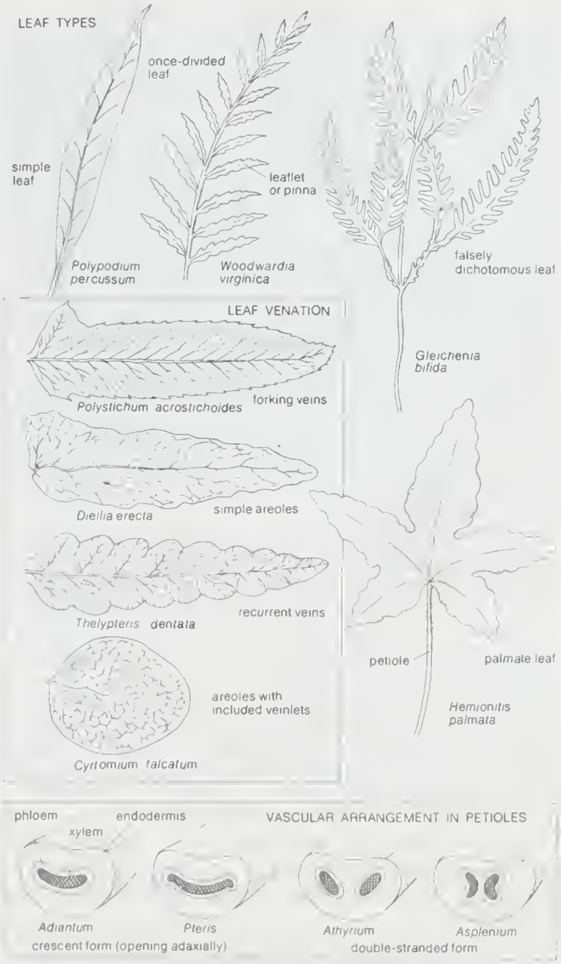

Figure 5: Fern leaves, showing leaf types, leaf venation, and internal petiole vascularization.

Drawing by M. Pahl

Leaf position

Leaf stalk. Fern leaves vary in the relationship of the petiole, or leaf stalk, to the blade (the expanded part of the leaf). Many strap-shaped leaves essentially have no petiole and are described as sessile; broad, ovate, or triangular leaves commonly have a pronounced leaf stalk, called a stipe, and are termed petiolate or stipitate. Narrowly elongated leaves in ferns are usually erect, spreading, or, in certain epiphytes, pendent. Leaves that are broadly ovate or triangular tend to be borne at right angles to the incident light. Broad-leaved ferns thus become more or less bent at the blade base, with an arch at the top of the petiole.

Anatomically, the petioles or stipes of fern leaves show nearly as much diversity in cross-sectional pattern as do the stems. The simplest vascular strands of fern petioles are commonly crescent-shaped, single bundles. In more and more elaborate petiolar patterns, the crescent takes on the form of the Greek letter omega (Ω), opening adaxially (*i.e.,* upward or toward the central axis of the plant). The latter shape, with many variations, occurs widely among ferns, especially those considered on other grounds to be primitive. Double-stranded ferns (the omega now divided into two parts and unconnected below) are usually associated with more specialized genera (*e.g., Athyrium, Thelypteris*). Any of the generalized patterns may exist as broken-up strands; the separation is commonly associated with size, small leaves having only three to nine strands, large leaves of tree ferns having many. Petiolar vascular bundle shapes have been found to be so definitive as to have a certain value in separating fern genera and families.

Tissues. At the tissue level the leaf blades have certain differences from those of other plants, but the same general picture prevails. There are an upper and a lower epidermis, the latter with many stomates (microscopic pores). In between, the mesophyll is usually composed of cells with large intercellular spaces. In thicker leaves, the upper mesophyll is composed of palisade cells—elongated cells arranged parallel and oriented with the long axis vertical to the leaf surface. The veins range from the massive major midribs, or rachises, which have well-defined xylem, phloem, pericycle, and endodermis, to the delicate capillaries represented by little more than a single file of tracheids that sometimes ends in a cluster of somewhat modified tracheids. Underneath a sporangium or sorus, the veins may become dilated and multilayered (so-called fertile veins). In many ferns all or nearly all of the photosynthesis is accomplished by the epidermis, the mesophyll having been eliminated in evolution. An example is the common maidenhair fern (*Adiantum pedatum*), the blade of which, between veins, is mainly made up of only two layers, the upper and the lower epidermis, in which most photosynthesis occurs.

Indument on fern leaves

The indument of fern leaves may be like that of the stem, but usually the hairs or scales are fewer, more widely separated, and smaller, or they may be of a different type. Numerous ferns are described as having glabrous (bald) leaf blades, but many of these actually have at least a few microscopic hairs, which are usually glandular and appressed to the blade surface.

Comparisons with leaves of other plant groups. The fern leaf, or pteridophyll, differs from the "true leaf" (euphyll) of the flowering plants in its vernation, or manner of expanding from the bud. In the ferns, vernation is circinate; that is, the leaf unrolls from the tip, with the appearance of a fiddlehead, rather than expanding from a folded condition. It also differs in its venation, which usually is free or simply reticulate rather than being highly complex and made up of areolae containing numerous branched, free-ending veinlets.

Fern leaves differ from the leaves (sphenophylls) of conifers and horsetails in that fern leaves usually display a well-developed central midrib with lateral vein branches rather than a dichotomous, midribless pattern or a simple vein in a narrow, needlelike, or straplike leaf. Although a few ferns that have narrow leaves also have only a single central vascular strand (*e.g.*, certain species of *Schizaea*), these can usually be distinguished readily from the scale-like or awllike leaves (microphylls) of club mosses on the basis of other characteristics, such as the position of the sporangia and the mode of leaf development. A few genera of ferns (*e.g.*, sword ferns, *Nephrolepis; Jamesonia; Salpichlaena;* and climbing ferns, *Lygodium*) have members with more or less indeterminate (*i.e.*, continuous) leaf growth accomplished by periodically quiescent buds. Fern leaves, however, are mostly determinate; that is, they stop growing when they reach maturity. Leaves grow from apical cells in most ferns, and these delicate embryonic cells are protected by the curled-over spiral of the crosier (unrolling leaf tip) and by hairs or scales. When the blade formation is complete, there is no longer an embryonic tip.

In overall length, mature leaves vary from 1 or 2 millimetres (0.04 or 0.08 inch) in certain filmy ferns (Hymenophyllaceae) to 30 or more metres (100 feet; family Gleicheniaceae). In terms of overall size, the most massive frond is that of the elephant fern (*Angiopteris*), with fronds more than 5 metres long and petioles 15 centimetres in diameter.

Types of spore-producing structures

Sporangium and sorus. *The sporangium.* The spore cases, or spore-producing structures, in ferns range from globose, sessile (nonstalked) organs more than 1 millimetre in diameter down to microscopic stalked structures, the capsules of which are only 0.3 millimetre in diameter. The former are known as eusporangia, the latter as leptosporangia. Eusporangia occur in the classes Ophioglossopsida and Marattiopsida, and leptosporangia occur in the majority of the species in the class Filicopsida. There are, however, many intermediate forms between the two types of sporangia, and these are known in various primitive species of the Filicopsida, such as members of the family Osmundaceae.

The capsule wall in eusporangia tends to be relatively massive, made up of two layers or more. In leptosporangia, on the other hand, the wall is thin and, at least at maturity, composed of one layer of cells. Opening of the capsule in eusporangia, such as those of the genus *Botrychium*, is accomplished by separation along a well-differentiated line of dehiscence (opening); but in most typical leptosporangia, except for a few stomial ("mouth") cells that separate along one side, the process of dehiscence tears the cells apart more or less irregularly.

The opening process in eusporangia is the result of a generalized stress on drying walls, the cells of which are differentially thickened. There is no mechanism to throw the spores, and they are simply carried away by the wind. In contrast, leptosporangia display more or less specialized bows, or annuli, usually consisting of a single row of differentially thickened cells. Apparently, the mechanical force for opening and for throwing the spores derives entirely from these annular cells; all the other capsule cells are thin-walled and unmodified. The stresses imposed by the drying of the annular cells result in the collapse of the outer sides of the cells, thus straightening out the annulus and ripping the soft lateral cells of the capsule apart. As the annular cells continue to be deformed by the cohesive forces of the increasingly tense water molecules within, the spore case completely opens. Finally, the cohesive capacity of the water molecules is exceeded, the water film between the outer walls of the annular cells breaks, and the entire annulus snaps back to its original position, tossing the spores into the air.

Most primitive sporangial types are stalkless, or sessile. If a stalk is present at all, it is merely a slightly raised multicellular area at the base of the sporangial capsule. In typical leptosporangia, however, there commonly are well-developed stalks, and these are often extremely long and narrow (*e.g.*, as in *Davallia* and *Loxoscaphe*), made up of only one or two rows of cells and often 1.7 to 2 millimetres in length.

The trend in sporangial evolution is evidently from solitary large capsules to more and more elaborate groupings of smaller sporangia. These changes are accompanied by the appearance of such refinements as paraphyses and indusia. Paraphyses are sterile structures that grow among or on the sporangia. Indusia are papery, tentlike structures that cover the sori (clusters of sporangia).

The sorus. Hand in hand with the reduction in size of single sporangia are seen more and more complex aggregations of sporangia known as sori. The meristematic area—the region of new cell growth—that produces them may continue its activities over a number of weeks, producing sporangia of all ages, older ones being pushed aside as new ones mature in their turn. When sori develop on the leaves of house ferns, they are often mistaken for tiny insects (young stages) or a fungus disease (older stages) rather than recognized as organs necessary for the normal reproduction of the plant.

Evolution of the sorus

The stages in progressive evolution of sori can be depicted as follows: (1) simple clusters of sporangia, these more or less coalesced (family Marattiaceae) or separate (Gleicheniaceae), all of them maturing at the same time, (2) gradate clusters of sporangia, the outermost ones maturing first, the innermost last, and (3) mixed clusters of sporangia, all ages present, the younger ones arising from the same meristematic zones as the older ones. The adaptive significance of this change is probably related to the duration of spore production, the mixed character of the more advanced sori extending the period beyond that of solitary sporangia or of simple, simultaneously maturing sori.

Drawing by M. Pahl from (top) F. C. Steward, *About Plants: Topics in Plant Biology* (1966), Addison-Wesley, Reading, Mass., and (bottom right) P. Martens & N. Pirard, "The Glandular Organs of *Polypodium virginianum*," *La Cellule*, 49(3) 383–406 (1943)

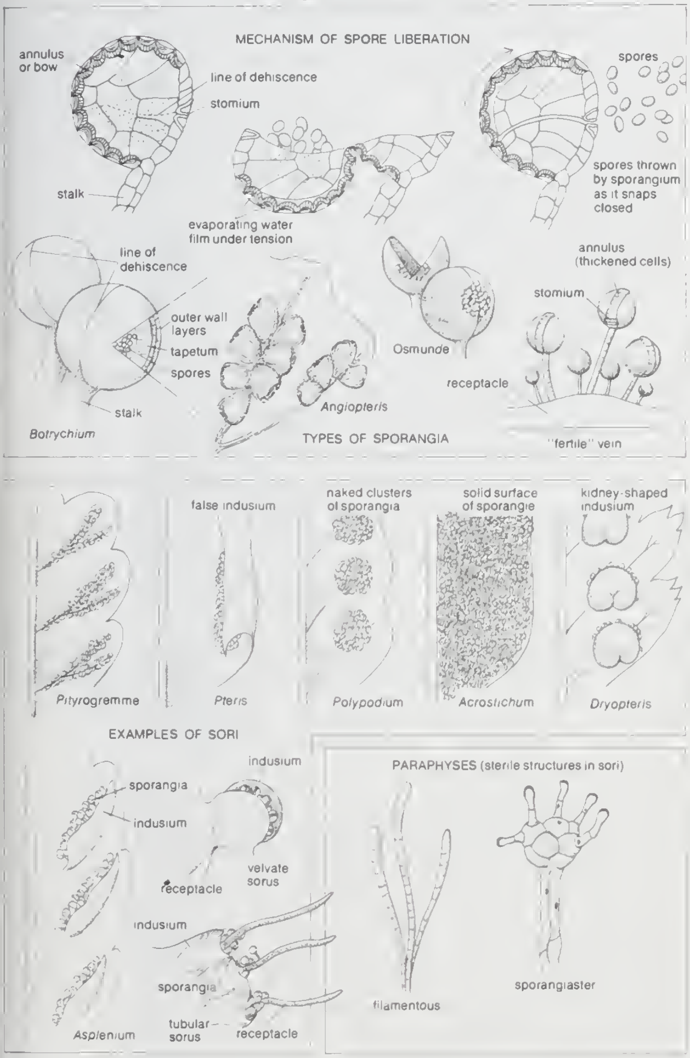

Figure 7: Fern sporangia, their arrangement into sori, and other structures found in the sorus.

Sporangia and especially sori have traditionally provided the most important characters for fern classification. Indeed, many unrelated ferns were once classified together because of what are now believed to have been coincidental convergences in soral structure. Between one-half and two-thirds of the species of ferns have one or another of the following six soral arrangements: (1) A linear arrangement of sporangia along veins, avoiding the leaf area between the veins, is found in many fern genera, especially in the genus *Pityrogramma*. (2) A line of sporangia along the leaf edge, protected usually by a rolled-over and modified laminar margin, is represented by *Pteris*. (3) Round and naked sori (*i.e.,* without an indusium) are found in *Polypodium*. (4) An arrangement of large sori that usually expand over the entire undersurface of the blade or pinna is represented by *Acrostichum*. Such sori probably arose by the fusion of smaller clusters of sori. Of the many arrangements of indusiate sori (*i.e.,* sori that are protected by indusia, or special scalelike structures), two of the most widespread are (5) a linear or oblong sorus along a vein covered from one side by a narrow indusium, which is represented by *Asplenium*, and (6) a sorus that is round but covered with a kidney-shaped or shieldlike indusium, which is represented by *Dryopteris*.

Variety in structure of indusia

The indusium. Protection of the sporangial cluster from exposure, drying, and other hazards is accomplished in various ways, such as by the formation of the sori in grooves or pockets or by the production of various forms of covers. One is the so-called false indusium, a rolled-over leaf margin under which sporangia form and mature. The true indusium is a separate and unique formation, the structural origins of which are not clear, that constitutes a more or less papery covering over the sorus. A widespread type of indusium among members of the family Cyatheaceae is one shaped like a cup, which arises around the base of the sorus, often enclosing the sorus until the sporangia are mature (*e.g., Cyathea*). In some genera, marginal sori are protected by a two-lipped, or valvate, indusium (*e.g., Dennstaedtia, Dicksonia, Hymenophyllum*). When sori fuse laterally to form continuous lines, or coenosori, any indusia also tend to fuse.

Paraphyses. Approximately one-third of fern species have paraphyses of one type or another. These are sterile hairs or scales intermixed with the sporangia, and they are, like indusia, believed to perform a protective function. Paraphyses usually are hairs or modifications of hairs that arise among the sporangia or on the sporangial stalk or capsule. In various genera of ferns, the paraphyses have proved to be helpful sources of taxonomic data.

CYTOGENETICS

Chromosome numbers and polyploidy. The study of chromosomes, hybrids, and breeding systems has revealed much of value in understanding ferns. The chromosomes of ferns tend to have high base, or x, numbers, ranging from approximately 20 to 70, with the majority between 25 and 45. The familiar genus *Osmunda*, for example, has $x = 22$, *Pteris* has 29, *Asplenium* 36, *Dryopteris* 41, *Botrychium* 45, and *Pteridium* 52. Among homosporous ferns, exceptions to the rule of high chromosome numbers are rare; in one species of filmy fern (*Hymenophyllum peltatum*), $x = 11$, the lowest number reported. Among heterosporous ferns, however, the situation is conspicuously different, and all have low base numbers (*Marsilea*, $x = 10$, 13, or 19; *Salvinia*, $x = 9$; *Azolla*, $x = 22$).

The explanation for the difference traditionally adopted by cytologists is that the high numbers in homosporous ferns arose from polyploidy, the repeated duplication of whole sets of chromosomes. Indeed, some workers regard homosporous ferns as nearly 100 percent polyploid. An alternative hypothesis should also be considered, however; namely, homosporous ferns were primitively high numbered, and heterosporous ferns derived their low numbers through reduction. Apparently the ferns do not need all their chromosomes; recent evidence has shown a considerable degree of "gene silencing."

The base chromosome numbers (indicated by the symbol x) have been used for classification purposes. Commonly, the base number is uniform for a genus or family, or it ranges around a given number. More rarely, the number varies drastically, as in the genus *Thelypteris*, which has x numbers ranging from 27 to 36, or *Lindsaea*, with x numbers from 34 to about 50. So much variation in the chromosome base number suggests that the "genus" concerned may be unnatural or that it may be very ancient, with intermediate numbers having disappeared (*e.g., Dennstaedtia*), or that it is in a state of active evolution (*Thelypteris*).

Simple polyploid series—multiples of the base number—are prevalent among ferns, and a few species are reported to have forms or races that are diploid (with two times the base number of chromosomes), tetraploid (four times), and hexaploid (six times). For example, the fragile fern, *Cystopteris fragilis*, has races with the number of chromosomes per nucleus in the sporophyte generation—represented by $2n$—equal to two, four, and six times the base number of $x = 42$; or $2n = 84$, 168, and 252. Species with both diploid and tetraploid forms are common, especially among widespread, abundant ferns. In most cases the cytological races are differentiated on quantitative characters, especially the sizes of such cells as spores, epidermal guard cells (cells next to stomates), and hair cells.

Hybridization. In certain temperate fern genera, such as spleenworts (*Asplenium*), wood ferns (*Dryopteris*), and holly ferns (*Polystichum*), hybridization between species (interspecific crossing) may be so frequent as to cause serious taxonomic problems. Hybridization between genera is rare but has been reported between closely related groups. Fern hybrids are conspicuously intermediate in characteristics between their parents, and simple dominance of single characters is unusual. Occasionally, when the interspecific crosses involve strongly different characteristics, the hybrid displays an irregularity in expression of these characteristics, often involving marked asymmetry. The majority of hybrids are sterile and reproduce, if at all, only by vegetative propagation.

Reproduction in sterile fern hybrids

Reproduction in sterile fern hybrids is also accomplished by the process of apogamy, in which spores possessing the same chromosome complement as the sporophyte are produced (normal spores have only half the chromosome number as the parent plant cells). These unreduced spores (with the $2n$ number of chromosomes) are viable and germinate into normal-appearing gametophytes that may or may not form sex organs. The hybrid gametophytes do not, however, undergo normal sexual fusion. Instead, the meristematic (cell-producing) region of the prothallium simply buds off a new sporophyte, and there is a direct conversion from gametophyte to sporophyte generation.

In most fern hybrids the spore mother cells are unable to form bivalents (chromosome pairs) at meiosis, and reduction division results in irregular, deformed, and inviable spores. In the sporangia of most apogamous ferns, however, automatic doubling of chromosomes occurs by endomitosis (duplication of chromosomes without formation of two nuclei), and each of the spore mother cells has a restitution nucleus—one with doubled chromosomes. In these doubled sporangia there are, therefore, only 8 spore mother cells rather than the usual 16, and they undergo meiosis, producing viable diploid spores. Apogamous ferns are known in a number of genera of higher ferns in various families, including *Adiantum, Asplenium, Cheilanthes, Dryopteris, Pellaea, Polypodium,* and *Pteris.*

Allopolyploid hybrids

Besides apogamous hybrids, there are numerous demonstrated or suspected "allopolyploid hybrids," which are believed to have originated by doubling of the chromosomes of sterile crosses. These are intermediate in their characteristics between well-known parental species and behave like normal, divergent species, alternating sporophytes with gametophytes and undergoing normal meiosis and fertilization. Genera with frequent hybridization often exhibit a variety of chromosome numbers that are multiples of the generic base number. One of the best examples is the tropical genus *Anemia,* with the base number of 38 and species with 76, 114, 152, 190, and 266.

Both apogamous and allopolyploid hybrids may enjoy wide geographic ranges and occur in as great abundance as normal species. Both types of hybrids are also capable of creating additional hybrids by backcrossing (to the parent species) or by crossing with other species. In apogamous ferns it is assumed that the sperm are generally viable and capable of fusing with eggs of other, normal species. In total, hybrids—sterile, apogamous, and allopolyploid—may make up as many as 25 percent of the different kinds of ferns in a given flora.

Curiously, in spite of the high number of ferns that are epiphytic (growing on trees), nearly all the fern hybrids are terrestrial or epipetric (growing on rocks); hybridization is very rare among epiphytes. The reason for this phenomenon is not yet clear; it could be simply that the mosses and decaying leaves on tree trunks and branches may keep the individual gametophytes apart, whereas on muddy banks gametophytes of different species may be in close proximity.

ORIGIN AND EVOLUTION

Fossil record. Fernlike characteristics are known to be combined in numerous fossils coming from geologic strata as old as the Devonian (beginning 408 million years ago). The Carboniferous Period (360 to 286 million years ago) was a time of great evolutionary experimentation in ferns, but nearly all those groups are now extinct. Modern ferns, however, are relatively uniform in basic structure, and they share a large number of characteristics, combined in a distinctive way. All the living families, with the possible exception of the Ophioglossopsida and the Marattiopsida, possess a ground plan of correlated characteristics that seems clearly to bind them together as an assemblage that is monophyletic (*i.e.,* having one evolutionary line). In spite of this, the ferns still display wide variation.

The norm of modern ferns is so distinctive that the vast majority of them can be recognized immediately as members of this plant division. Nevertheless, various workers in the past, especially among paleobotanists, have singled out fossil fragments and speculated that they represent fern ancestors, sometimes giving them such names as *Archaeopteris* (primitive fern) or *Protopteridium* (first fern). One or two extant genera can be traced to direct ancestors in the Carboniferous, but for the most part the fossil record shows no immediate ancestors of modern ferns; the first relatives of today's ferns in the fossil record are usually classifiable into living groups.

The earliest true ferns arose during Carboniferous times, or perhaps a few in Devonian, and have been classified in four families—Marattiaceae, Osmundaceae, Gleicheniaceae, and Schizaeaceae. Several extinct groups of the Carboniferous Period and the Permian Period that followed—Coenopteridaceae, Anachoropteridaceae, Tedeliaceae, Sermayaceae, Tempskyaceae—represent related lines of evolution, but there are no intermediate examples to show close ties with any of the modern families of ferns. The immediate ancestors of the extinct seed ferns (pteridosperms) may also have been the immediate ancestors of modern ferns, judging from numerous data on sporangial arrangements and shapes as well as on leaf anatomy. What used to be considered impressions of fern leaves from fossils dating from the Carboniferous have been shown in many cases to have borne seeds or to have been associated with seed-bearing plants.

Antiquity of modern ferns

By the time of the Mesozoic Era (beginning 245 million years ago), the modern fern families were well established, and there are fossil records of the families Osmundaceae, Marattiaceae, Schizaeaceae, Matoniaceae, Dipteridaceae, Adiantaceae, Cyatheaceae, Aspleniaceae, Marsileaceae, Azollaceae, and Salviniaceae.

Evolutionary development. Despite a relatively large number of theories, the actual origins of the vegetative organs of ferns are still unknown. It is usually suggested that the original fern stem was protostelic (its stele having no pith or leaf gaps), but this is not necessarily true of the immediate ancestor of modern ferns. In fact, it is conceivable that "eustelar" stems, with secondary growth (*i.e.,* growth in thickness, as in the stems of modern conifers and woody flowering plants), gave rise to modern fern stems through reduction and disappearance of the secondary growth and replacement of the stele by overlapping leaf traces (the vascular bundles from stele to leaf).

The leaf is equally or even more problematic as to its ultimate origin. Various hypotheses have been offered, of which the telome theory (that the leaf arose from fusions and rearrangements of branching stem systems) and the enation theory (that the leaf arose from simple enations, or outgrowths) are the two most popular. The true story seems to be lost in antiquity and perhaps will never be known. Modern fern leaves with their characteristic fiddleheads, acropetal growth (*i.e.,* "seeking the apex," the leaf tissues maturing from the base toward the tip, where the youngest tissues are produced), and pinnate structure, are nevertheless quite distinctive. They differ in numerous respects from sphenophylls, such as those of conifers and sphenophytes, and from euphylls, such as those of flowering plants. It is possible that these leaf types did not originate in the same way and even that different examples of each had different origins.

CLASSIFICATION

Annotated classification. The classification presented here is derived from J.A. Crabbe, A.C. Jermy, and J.T. Mickel (1975) and T.N. Taylor (1981). Numbers given for the species are only rough approximations of living groups.

DIVISION FILICOPHYTA (true ferns)

Spore-dispersed vascular plants with free-living sporophyte and gametophyte generations, the sporophyte dominant; leaves frondose, circinate (expanding by unrolling), possessing petiole (stalk), midrib, and blade, the latter or its subdivisions with free or netted venation patterns; sporangia solitary or variously soriate (in clusters) and borne upon the leaf blades or their modified parts, marginally or abaxially (on the undersurface, or surface facing away from the central axis of the plant); stems upright or creeping, mostly lacking secondary thickening, and bearing roots; meristems (growing points) protected by hairs or scales; gametophytes monomorphic (all with similar structure), exosporic (developing outside the spores), hermaphroditic (bisexual), and either surficial (growing on the surface) and photosynthetic or subterranean, saprophytic, and symbiotic with fungi; or gametophytes dimorphic (with two forms), endosporic, and antheridial (male) or archegonial (female).

Class Ophioglossopsida

Leaf divided into sterile and fertile segments, leaf base more or less clasping the stem; eusporangiate (with unstalked, globose sporangia); homosporous; plants mostly small and fleshy, occurring in early ecological succession; not known as fossils.

Family Ophioglossaceae (adder's-tongue, grape ferns, moonworts). Leaf blade undivided to forked or pinnately lobed or divided; veins reticulate (netlike) or free; sporangia borne upon unbranched "spike" or many-branched fertile structure arising from base of the blade or blade stalk; 3 genera (*Botrychium, Helminthostachys, Ophioglossum*) with about 55 species.

Class Marattiopsida (giant ferns)

Leaves pinnately divided, pulvinate (enlarged or swollen at attachment point of leaflets) in living genera, and with well-developed, fleshy stipules (appendages at leaf base); sporangia eusporangiate, in sori, or more or less coalescent in synangia (clusters); homosporous; mostly massive, fleshy ferns of tropical forests.

Family Marattiaceae. Six genera, including *Angiopteris, Marattia,* and *Danaea* with about 100 species (the extinct Carboniferous and Permian *Psaronius* belongs here).

Class Filicopsida

Leaves nonpulvinate and nonstipulate; sporangia leptosporangiate (stalked), solitary, or in sori; if soriate, then with or without indusia (protective coverings) and paraphyses (other sterile structures); mostly medium-sized sclerenchymatous (with hardened tissues) plants with cosmopolitan distribution; the class includes most common ferns.

Order Filicales

Terrestrial, epiphytic, or aquatic, homosporous ferns.

Family Osmundaceae (royal ferns). Sporangia on axes of much-reduced segments or along veins on unmodified blade, maturing nearly simultaneously, intermediate between eusporangia and leptosporangia, the annulus a lateral patch of thick-walled cells; petioles with distinct dilations; 3 genera (*Osmunda, Todea, Leptopteris*) and 20 species, plus 5 to 10 extinct genera from the Carboniferous and Permian periods.

Family Plagiogyriaceae. Leaves 1-pinnate, dimorphic, with trophophylls (sterile fronds) and sporophylls (fertile fronds), the latter contracted and containing scattered sporangia with strongly oblique annuli (rings of special cells); petiole bases swollen; stem apex and young leaves covered with mucilage from secretory hairs; 1 genus (*Plagiogyria*) with about 30 species, distributed in tropical regions.

Family Stromatopteridaceae. A strange, small, terrestrial fern with little organ differentiation; rhizome and roots merging into aboveground fronds without a sharp distinction; thought by some botanists to be related to the Psilotaceae, a family of psilotophytes, but most consider it related to the fern family Gleicheniaceae; 1 genus and species, *Stromatopteris moniliformis.*

Family Gleicheniaceae (forking ferns). Leaves mostly sprawling over other vegetation, falsely dichotomous, the segments mostly narrowly lobed; sporangia with oblique annuli and organized in simple sori; stems creeping, protostelic (its stele lacking pith and leaf gaps); *Gleichenia, Dicranopteris,* and 3 other genera with about 150 species, distributed in the tropics.

Family Matoniaceae. Leaves either fanlike, with lobed, narrow segments, or climbing, with long midribs; sporangia with oblique annuli, the simple sori covered by a thick, peltate, indusium-like structure; 2 genera (*Matonia* and *Phanerosorus*) with about 4 species, distributed in the Old World tropics.

Family Dipteridaceae (umbrella ferns). Leaves fan-shaped, venation free or finely reticulate with free, included veinlets; sporangia with oblique annuli; sori small, with paraphyses; stem with solenostele (stele with 1 leaf gap), covered with bristlelike hairs; 1 genus (*Dipteris*) with about 8 species.

Family Cheiropleuriaceae. Leaves dimorphic, with complex reticulate veins, the sterile leaves midribless, once or twice forked; sporangia with oblique annuli and 4-rowed stalks; sorus acrostichoid (covering the underside of the leaf) and with paraphyses; stem protostelic or solenostelic; 1 genus and species (*Cheiropleuria bicuspis*), distributed in the Old World tropics.

Family Polypodiaceae (true polypodies). Plants mostly epiphytic; stem scales often clathrate (latticed); leaves usually lobed or simple, with articulate (having a swollen point of separation) petioles and reticulate veins; sporangia with typical erect annuli, numerous, borne in round sori; spores bilateral, golden; gametophyte cordate (heart-shaped), nongemmiferous (not producing gemmae, tiny clusters of cells that break off and form new gametophytes); genera include *Polypodium, Pyrrosia, Platycerium,* and 30 to 50 others (depending upon the authority consulted) with 550 species.

Family Grammitidaceae (dwarf polypodies). Shaded rain forest epiphytes; leaves nonarticulate (not falling off); veins free; stem upright; stem scales with uniform walls; spores tetrahedral-globose, green; gametophyte narrowly cordate to ribbon-shaped, gemmiferous; *Grammitis* and 8 to 10 additional genera encompassing 500 species. (This family was formerly considered a subfamily of the true polypodies.)

Family Schizaeaceae. Leaves frondlike, twining, or grasslike; sporangia often borne on specialized pinnae, or leaf segments; sporangium with its annulus composed of a subapical uniserial ring of thickened cells; 6 genera (including *Anemia, Lygodium, Schizaea*) with about 160 species, mostly tropical.

Family Parkeriaceae (aquarium ferns). Plants soft, rooted in mud or floating; leaves 2- or 3-divided, upright or spreading; veins anastomosing (netted); 1 genus (*Ceratopteris*) having 4 species.

Family Platyzomataceae. Somewhat intermediate between the Schizaeaceae and Adiantaceae; 1 genus and species, *Platyzoma microphylla,* of northern Australia.

Family Adiantaceae. Sporangia in lines along the veins or on or at the vein tips, either unprotected, in grooves, covered by a more or less rolled leaf margin (called the false indusium), or rarely acrostichoid; sporangia with typical erect annuli; spores mainly tetrahedral, nonperisporial (having no outer jacket); about 60 genera containing 850 species; cosmopolitan in distribution.

Subfamily Adiantoideae (cliff brakes, maidenhair ferns, lip ferns). Mainly small and xerophytic (with adaptations to dry habitats); epipetric (growing on rocks) or terrestrial and rigid; leaves 1- to multi-pinnate; veins mostly free; *Adiantum, Cheilanthes, Pellaea, Pteris,* and 45 other genera with a total of 750 species.

Subfamily Vittarioideae (shoestring ferns). Plants leathery, epiphytic; leaves simple, pendent; veins anastomosing; *Vittaria, Antrophyum,* and 5 other genera with 100 species.

Family Lophosoriaceae. A primitive, trunkless tree fern having a short, creeping rhizome with long, golden hairs; fronds finely divided; sori round and lacking an indusium; probably related to the Metaxyaceae; 1 genus and species, *Lophosoria quadripinnata,* of high elevations in tropical America.

Family Metaxyaceae. A primitive, trunkless tree fern with a short, creeping rhizome bearing golden hairs; fronds once divided; sori round, with no indusium; probably related to the Lophosoriaceae and more distantly to *Dicksonia* in the family Cyatheaceae; 1 genus and species, *Metaxya rostrata,* of low elevations in tropical America.

Family Cyatheaceae (tree ferns). Very large, terrestrial ferns, the rhizomes trunklike and upright; indument of hairs or scales; sori indusiate, the indusium marginal and 2-lipped, or medial with indusium surrounding sorus from below; spores mostly tetrahedral, nonperisporial; genera number 7 (including *Dicksonia, Cibotium, Cyathea*) with nearly 1,000 species.

Family Dennstaedtiaceae (cup ferns, bracken). Terrestrial, medium-size to large ferns, the rhizome short to long and creeping; indument of hairs, rarely scales; sori mostly marginal with 2-lipped indusia; spores mostly tetrahedral, nonperisporial; genera number 16 (including *Dennstaedtia, Pteridium, Hypolepis, Lindsaea*) with about 400 species, mainly tropical in distribution.

Family Hymenophyllaceae (filmy ferns). Rain forest epiphytes; mostly tiny ferns with blades only 1 or 2 cells in thickness between veins; spores globose, green; gametophyte ribbon-shaped or filamentous, gemmiferous; principal genera are *Hymenophyllum* and *Trichomanes;* numerous subgenera or splinter genera are maintained by some authorities, resulting in a number of genera from 2 to 35; there are 500 species.

Family Loxsomataceae. Rare primitive ferns with sori projecting from leaf margin, borne in tubular involucra (protective coverings), and with sporangia on an elongated receptacle as in the Hymenophyllaceae, to which it probably is related; 2 genera, *Loxsoma,* with 1 species, in northern New Zealand and *Loxsomopsis,* with 3 species, from Costa Rica to Bolivia.

Family Aspleniaceae. Rhizomes mainly scaly; sori abaxial with peltate (shieldlike), reniform (kidney-shaped), oblong, or linear indusia; sporangia with typical leptosporangiate annuli; spores mostly bilateral, provided with perispore; the most common and largest family of ferns, cosmopolitan in distribution and containing about 85 genera (including *Thelypteris, Asplenium, Dryopteris, Polystichum, Elaphoglossum*) with approximately 4,000 species.

Family Blechnaceae (chain ferns). Rhizome scales nonclathrate; sori along midveins, the indusia opening inward; young foliage commonly red, turning to green; genera number 5 to 10 (including *Blechnum, Woodwardia*) with 250 species.

Family Davalliaceae. A group of largely epiphytic ferns of tropical or warm temperate regions; old fronds or leaflets fall from the plant; rhizomes scaly; sori abaxial, usually round, with a reniform or nearly tubular indusium; closely allied to the Aspleniaceae; genera number 14, including *Davallia,* the rabbit's-foot fern, and *Nephrolepis,* Boston fern relatives; about 120 species.

Order Marsileales

Aquatics with long, usually rooted rhizomes; leaves long-petioled with 2 or 4 terminal leaflets, or none; sporangia contained in sporocarps (nutlike receptacles) along petiole; heterosporous.

Family Marsileaceae. Three genera—*Marsilea* (waterclover), *Pilularia, Regnellidium*—with about 75 species.

Order Salviniales

Floating aquatics with small, rounded sporangia contained in saclike indusia; leaves sessile; heterosporous.

Family Salviniaceae (water spangles). Leaves in whorls of 3, of which 2 are oval in outline and floating, with complex hairs on the top surface, the third finely divided and hanging rootlike in the water; true roots absent; 1 genus (*Salvinia*) with 10 species.

Family Azollaceae (mosquito fern). Leaves alternate, overlapping, vertically divided into 2 lobes, the upper floating, the lower submersed; true roots present; 1 genus (*Azolla*) with 5 species.

Critical appraisal. The classification of ferns has been in a state of flux over the past several decades, but there is increasing agreement over relationships between genera. The differences in classification increasingly have to do with the level of categories deemed appropriate. Many fern groups show their relationships more by connecting links than by single character clusters shared by all members; thus many of the groups are difficult to characterize with a single description.

Relationship of ferns to "fern allies"

Some authorities still regard the ferns as being related to club mosses (Lycophyta), horsetails (Sphenophyta), and whisk ferns (Psilotophyta) and refer to all of the latter as "fern allies." In many respects, pertaining especially to their life cycle, the ferns do indeed resemble the so-called fern allies, but in other respects, especially those having to do with the vegetative body of the plant, ferns are quite distinct. (W.H.Wa./J.T.Mi.)

Lycophyta (club mosses and allies)

The Lycophyta are generally considered to constitute a division of spore-bearing vascular plants comprising the club mosses and their allies, living and fossil. Present-day lycophytes are grouped in 4 genera (some botanists divide them into 10 or more): *Lycopodium,* the club mosses or "ground pines"; *Selaginella,* the spike mosses; the unique tuberous plant *Phylloglossum;* and *Isoetes,* the quillworts. There are more than 1,000 species, widely distributed but especially numerous in the tropics. Representative extinct genera are *Lepidodendron* and *Sigillaria,* which were tree lycophytes, and *Protolepidodendron,* a herbaceous *Lycopodium*-like plant. Lycophytes are known from rocks of the Devonian Period (beginning 408 million years ago) and perhaps of the Silurian (as many as 438 million years ago). The remains of *Lepidodendron* and other extinct lycophytes form most of the great coal beds of the world.

GENERAL FEATURES

Many of the ancient lycophytes, such as *Lepidodendron,* were trees that often exceeded 30 metres (100 feet) in height. The living genera are all small plants, some erect and others low creepers. Regardless of their size or geologic age, all share certain group features. Branching is usually dichotomous; that is, the shoot tip forks repeatedly. The two branches that result may be equal in length or may be of different lengths. The leaves are generally small, although they sometimes achieved a length of one metre (three feet) in the gigantic *Lepidodendron.* Generally each leaf, or microphyll, is narrow and has an unbranched midvein, in contrast to the leaves of the ferns and seed plants, which generally have branched venation. The sporangia (spore cases) occur singly on the adaxial side (the upper side facing the stem) of the leaf. The lycophytes generally bear conelike structures called strobili, which are tight aggregations of sporophylls (sporangium-bearing leaves).

LIFE CYCLE

In the lycophytes, as in other vascular plants, there is an alternation of generations between a small, sex-cell-producing phase (gametophyte) and a conspicuous, spore-producing phase (sporophyte). The members of one of the chief living genera, *Lycopodium,* are homosporous (with just one kind of spore). They have terrestrial or subterranean gametophytes that vary in size and shape depending on the subgenera (or genera of some authors).

Underground gametophytes of *Lycopodium*

Although *Lycopodium* gametophytes are rarely found in nature, enough is known about them to recognize two fundamental types, based principally upon their mode of growth and nutrition. In some species the gametophyte becomes a small, green plant with numerous lobes, growing on the surface of the soil; the time interval between spore germination and sexual maturity of the gametophyte may be eight months to a year. In other species, including nearly all those of the north temperate zone, the gametophyte is subterranean, slower growing, and dependent upon an associated fungus for continued growth. The yellow to brown underground plant may become carrot-shaped, rod-shaped, or disk-shaped and 1 to 2 centimetres (0.4 to 0.8 inch) in length or width. Generally, a gametophyte of this type remains subterranean, and five or more years are required before it becomes sexually mature.

Gametophytes are monoecious (bisexual); *i.e.,* the sperm-producing antheridia and the egg-producing archegonia occur on the same plant. Fertilization takes place after a flagellated sperm swims to the archegonium. The embryo, or young sporophyte, consists of a shoot, a root, and a food-absorbing outgrowth called a haustorial foot. Ultimately the sporophyte becomes physiologically independent of the gametophyte, and the latter dies.

The other main extant genera—*Selaginella* and *Isoetes*—are heterosporous (having two kinds of spores). Their gametophytes are microscopic and undergo most of their development while still within the spore wall (endosporic development). Definite strobili are formed in *Selaginella,* and the sporophylls generally differ from the vegetative leaves, although not as much as in the species of *Lycopodium* that form strobili. There are two types of sporangia in *Selaginella,* called microsporangia and megasporangia; the sporophylls associated with them are termed microsporophylls and megasporophylls.

Numerous microspores are produced in the microsporangium, and cell division within the microspore wall initiates male gametophyte development. These divisions may occur before the spores are shed from the microsporangium. Final development of the male gametophyte, or microgametophyte, usually occurs on the soil prior to the release of biflagellate sperm. Usually only four large megaspores are produced in a megasporangium. Development of the female gametophyte, or megagametophyte, also may begin while the megaspore is still within the megasporangium. Free nuclear divisions (without wall formation) occur for a time, but ultimately walls appear and the megagametophyte ruptures the megaspore wall. These

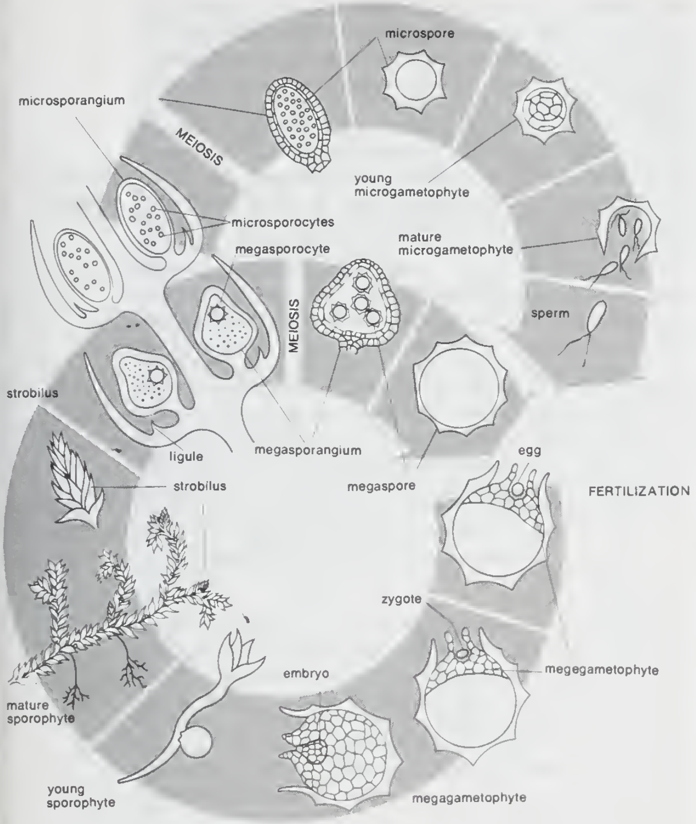

Figure 8: Life cycle of *Selaginella*.

final stages in development usually occur on the soil after the megaspore with the enclosed female gametophyte is shed from the megasporangium. Fertilization occurs when a sperm swims to an archegonium. The young sporophyte remains in physical contact with the megaspore and the enclosed female gametophyte tissue for some time.

The processes of sexual reproduction of *Isoetes* are very similar to those of *Selaginella,* except that the sperm are multiflagellate and many more spores are formed per sporangium. In fact, the microsporangia of some species are the largest among vascular plants and produce several thousand spores.

FORM AND FUNCTION

Lycopodium sporophytes

In growth habit, the sporophytes of *Lycopodium* species may rise erectly from a system of rhizomes (underground stems), or they may creep. Many are epiphytes; *i.e.,* they grow attached to tree branches or other supports. Branching is usually dichotomous, but in species with well-developed rhizomes one branch of a dichotomy usually becomes much longer and larger than the other and remains close to the surface. The shorter one may undergo several limited dichotomies, the ultimate upright branches terminating in strobili. The leaves may be spirally arranged or grouped in four vertical rows along the shoot. Each leaf has one unbranched midvein. Adventitious roots, initiated near the shoot tip, may grow within the stem cortex for some distance before emerging. The roots branch dichotomously, but no extensive root system is formed.

The stem is protostelic (without a central pith), but there is great variety in the disposition of xylem and phloem in the central vascular cylinder. Sporophylls may be aggregated into definite strobili, or there simply may be fertile and sterile regions along a stem, the sporophylls resembling vegetative leaves. Often the sporophylls of compact strobili differ from the vegetative leaves of the same plant.

Selaginella species have foliage leaves only a few millimetres long; they may be dark green or bluish and in some species are iridescent. As in *Lycopodium,* branching is usually dichotomous. The sporophyte may consist of several upright branches from a rhizome, prostrate branches creeping along the surface of the soil, or large, flat, erect, frondlike side branches from strong rhizome systems. The entire branch system often resembles a fern leaf. One distinctive feature of *Selaginella* is the rhizophore, a prop-like structure that originates at a point of branching and that forks dichotomously after making contact with the soil or a hard surface. Rhizophores are most readily seen in clambering species. Morphologically, the rhizophore is considered to be a root, although on occasion it can give rise to leafy branches if the normally leafy branches are cut off. Anisophylly (the occurrence of two sizes of leaves) occurs in most species of *Selaginella,* especially those of the wet tropics.

Ligules on leaves of *Selaginella*

Another distinctive feature in *Selaginella* is the presence of an unusual structure on the adaxial side of a leaf; this is the ligule, a peculiar tonguelike outgrowth from the leaf surface near the leaf base. Leaves of *Lycopodium* and *Selaginella* can be differentiated on this basis. The ligule, which appears very early in the development of a leaf, is a surprisingly complex structure at maturity. Its evolutionary origin is obscure. Functionally, ligules are believed to be secretory organs that, by exuding water and possibly mucilage, serve to keep young leaves and sporangia moist. Short-lived structures, they become shrunken and inconspicuous in older leaves. The ligule was a characteristic feature of the extinct giant lycophytes such as *Lepidodendron.*

Isoetes species have a plant body that is relatively small, consisting of a short axis and tufts of leaves and roots. Many species are similar in appearance to certain aquatic grasses, which are seed plants. The majority of species occur in the cooler regions of the world and are often immersed continuously in water. Each leaf is actually a sporophyll, bearing either a microsporangium or a megasporangium which is embedded in its base on the adaxial side. Each leaf also has a ligule, similar to that of *Selaginella. Isoetes* differs from both *Selaginella* and *Lycopodium* in the occurrence of secondary growth in the stem and the possession of a definite root-producing meristem. The sets of roots arise in a definite sequence, in contrast to the more or less irregularly produced roots of all other extant lower vascular plants. This sequence resembles that of its presumed ancestors *Lepidodendron* and *Pleuromeia.*

CYTOGENETICS

As in the ferns, the heterosporous representatives have much lower chromosome numbers than do the homosporous groups. Thus, *Selaginella* and *Isoetes* have $x = 9$ or 10 (*Selaginella*) and 11 (*Isoetes*), whereas *Lycopodium* and *Phylloglossum* have a wide range of higher numbers, which are correlated with sections or subgenera (or splinter genera): $x = 23$ (*Diphasiastrum*), 34 (*Lycopodium* in the strict sense), 35 (*Pseudolycopodiella*), 39 (*Lycopodiella*), 67 to 68 (*Huperzia* and *Phlegmariurus*), and 104 to 156 (*Palhinhaea*). *Phylloglossum* has $x =$ about 250. Hybridization is rare in *Selaginella* but common in *Isoetes* and the terrestrial species of *Lycopodium.*

EVOLUTION AND CLASSIFICATION

Fossil forms. The lycophytes represent a wide range of extinct and living plants that have contributed important data on evolutionary trends in primitive vascular plants. The earliest lycophytes included *Baragwanathia* and *Protolepidodendron,* dating from the early Devonian Period. Both were small herbaceous plants. During the Carboniferous Period, which followed (beginning 360 million years ago), the treelike forms of the Lepidodendrales appeared.

"Form genera"

Over the years, fossil parts of lepidodendronic plants have been discovered and assigned by taxonomists to so-called form genera, or organ genera: *Lepidophyllum* for detached leaf fossils, *Lepidostrobus* for fossil strobili. These form genera are now recognized as portions of one main fossil genus designated *Lepidodendron.* Some other lycophytes coexisting with the tree lycophytes were small herbaceous plants that resembled modern *Lycopodium* and *Selaginella* species.

Annotated classification. Groups marked with a dagger (†) in the listing below are extinct and known only from fossils.

DIVISION LYCOPHYTA (club mosses and allies)
Primitive, seedless vascular plants with true roots, stems, and leaves; sporangia associated with leaf bases, the fertile leaves often aggregated to form cones; distributed worldwide but concentrated in the tropics.

†Order Protolepidodendrales
Extinct herbaceous (rarely woody), homosporous lycophytes; about 8 genera, including *Baragwanathia* and *Protolepidodendron.*

†Order Lepidodendrales
Extinct tree lycophytes, therefore capable of secondary growth; heterosporous, with some strobili (cones) forming seedlike structures; about 6 genera, including *Lepidodendron* and *Sigillaria.*

Order Lycopodiales
Living and extinct plants with primary growth only; homosporous; 2 living genera, *Lycopodium,* with 200 species, mostly tropical, and *Phylloglossum,* with 1 species, restricted to Australia and New Zealand; includes the extinct *Lycopodites.*

Order Selaginellales
Living and extinct plants with primary growth only; heterosporous; the sole living genus is *Selaginella,* with nearly 800 species, widely distributed around the world; *Selaginellites* is an extinct genus.

Order Isoetales
Living and extinct plants with secondary growth; heterosporous, with endosporic gametophytes; *Isoetites* is an extinct genus; a specialized group of species from the high Andes Mountains is sometimes segregated as a distinct genus, *Stylites;* for many years the species of *Isoetes* were difficult to distinguish, but, since the discovery that frequent hybridization was obscuring the differences between species, they are more clearly understood; *Isoetes* includes more than 100 species in swampy, cooler parts of the world.

†Order Pleuromeiales
Extinct unbranched plants, with subterranean, rootlike rhizophores; heterosporous; a single fossil genus, *Pleuromeia.*

Critical appraisal. This group is now generally recognized as a division; in the past, however, it was commonly treated as a class, Lycopsida. Students of the Lycophyta are finding increasing evidence to support the division of *Lycopodium* and *Selaginella* each into two or more genera. *Lycopodium* has 3 to 11 groups that might be recognized as distinct genera, based on different chromosome numbers, spore sculpturing, and gametophyte morphology. Similarly, *Selaginella* is divided into two or three groups on the basis of differences in spores and leaves (those with two kinds of leaves and those with leaves all alike). The groupings appear to be natural, but it is too soon to say whether these subdivisions will receive general acceptance as genera among botanists.

Sphenophyta (horsetails)

The Sphenophyta, or Equisetophyta, are a division of primitive spore-bearing vascular plants. Most members of the group are extinct and known only from their fossilized remains. The sole living genus, *Equisetum,* is made up of about 15 species of very ancient herbaceous plants, the horsetails and scouring rushes. Extinct members of the division, some of which have been traced back as far as the Devonian Period (408 to 360 million years ago), include many herbaceous Equisetales, shrubby Hyeniales, vinelike Sphenophyllales, and trees of the family Calamitaceae.

GENERAL FEATURES

Sphenophytes, fossil and living, characteristically have whorled leaves and branches and conspicuously jointed stems, which in many cases are also ribbed. Reproductive structures are present in the form of greatly compressed stems called cones, or strobili, which form at the ends of branches.

The giant extinct horsetails (*Calamites*) were trees up to 1 metre (3 feet) in diameter and 30 metres (100 feet) in height. Their leaves—like those of extant horsetails—were arranged in spokelike whorls at regular intervals along the jointed stems. In the Sphenophyllales, an extinct order of scrambling sphenophytes, the leaves were wedge-shaped, with a repeatedly forking (dichotomous) venation system (sphenophylls). The order Hyeniales included shrublike plants with inconspicuous leaves arranged in rather indistinct whorls.

The living species of *Equisetum* are widely distributed in the Northern Hemisphere. Most of them are less than one metre (three feet) tall. There are reports of specimens of *E. giganteum,* from the American tropics, that attain a height of about 10 metres with a stem diameter of only 4 centimetres (1.6 inches); support is apparently provided by their habit of growing in dense stands in their natural environment. The majority of *Equisetum* species are found in wet or damp habitats, often in shaded locations along streams, ditches, and canals; some species, however, have become adapted to drier and sunnier conditions.

Equisetum habitats

The extant sphenophytes have had little economic importance. The extinct giant types contributed to the coal beds formed in the Carboniferous Period (360 to 286 million years ago). Living horsetails have been used as scouring agents, their cleansing value being attributed to the abrasive action of the silica-laden walls of certain of their cells. Silica is only one of several minerals that horsetails selectively accumulate in their bodies. Gold is another—up to 0.15 gram per kilogram (4.5 ounces per ton) of plants—not economically feasible to mine but a certain indication of the availability of such ore deposits in the soil. Horses foraging on stands of *Equisetum* have been known to die from severe intestinal inflammation.

LIFE CYCLE

Horsetails, like other vascular plants, display an alternation of generations: an asexual phase, represented by a sporophyte (the horsetail plant), and a sexual phase, the gametophyte, an inconspicuous, delicate, green plant. Each year, many gametophytes are initiated from spores, but apparently very few produce sporophytes in nature. Horsetails apparently survive mainly by vegetative reproduction rather than by a regular dependence on the sexual cycle.

Some horsetails carry terminal cones (strobili) on green aerial branches. Other species, however, have separate upright, aerial branches for vegetative and for reproductive shoots. In these species the strobilate branches appear first, and, after the spores are shed, the green vegetative shoots develop. The fertile components of the strobilus are called sporangiophores; each consists of a stalk bearing a flattened disk at its apex, on the lower edge of which is a ring of 5 to 10 sporangia, each one opening and shedding spores by a longitudinal slit on its inner side. The Carboniferous treelike horsetails and their smaller allies are believed to have possessed the most elaborate reproductive strobili known among the vascular plants.

Sphenophytes are homosporous, producing only one kind of spore. The spores have four bands, or elaters, which coil and uncoil in response to changes in humidity, assisting in

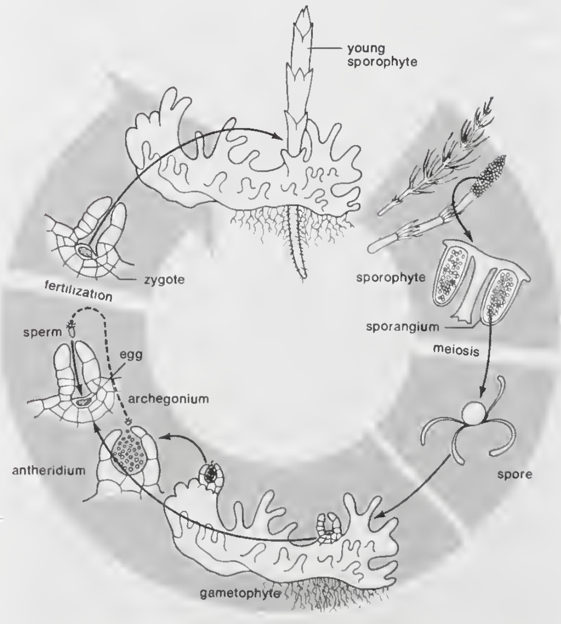

Figure 9: Life cycle of *Equisetum.*

the dispersal of the spores. Under low light intensity and high humidity, the spores germinate to form small, flattened, green gametophytes. After a period of development, these gametophytes come to resemble miniature green pincushions up to 3 centimetres (1.2 inches) in diameter. Eggs are produced in archegonia, at the bases of upright lobes on the gametophytes, and sperm are produced in antheridia, present on the lobes. The egg is fertilized in the archegonium by a sperm, forming a zygote which, by continued divisions, develops an embryo within the archegonium. The embryo (young sporophyte) is nourished by the gametophyte until it develops its own shoot and roots. One gametophyte may support two or more young sporophytes before it ultimately dies and decays.

FORM AND FUNCTION

Jointed structure of stem

The sporophyte of a typical sphenophyte consists of stem, leaves, and roots. The underground part of the stem (the rhizome) and the aerial part show the same basic organization. They consist of distinct segments united end to end at the nodes, which are the origins of the roots and leaves. (This jointed structure is the source of the alternative name Articulatae, which was applied to the Sphenophyta by some earlier authorities.)

The slender, herbaceous stems of *Equisetum* have hollow internodes. The whorled leaves are greatly reduced and nonphotosynthetic and are united laterally at each node to form a toothed sheath around the stem. Each leaf has a single, unbranched midvein. Secondary growth, by which girth increases annually, was characteristic of the extinct Calamitaceae and Sphenophyllales. In *Equisetum* the vascular strands are small and round, surrounding a large pith cavity. In the majority of species, the cell walls of the outer cell layer (epidermis) are thick and contain silica deposits. Branch buds are initiated at the nodes, but their subsequent development is dependent on the growth characteristics of the particular species. In relatively unbranched species, bud growth remains inhibited.

Spores develop in spore cases (sporangia), which are borne on sporangiophores. These are organized into strobili, which may be associated with sterile bracts (much reduced leaves)—as in Sphenophyllales and Calamitaceae—or may be without them (Hyeniales, Equisetaceae). Each sporangiophore in *Equisetum* has 5 to 10 sporangia. The entire sporangiophore may have arisen as a condensed, dichotomous branch system, with each sporangium occupying the end of a branch but lying parallel to the stalk of the sporangiophore.

CYTOGENETICS

Chromosome numbers in *Equisetum* are uniformly $x = 108$. Several hybrids are known, but all are sterile, since there is no doubling of the chromosome number to allow chromosome pairing and consequent production of viable spores.

EVOLUTION AND CLASSIFICATION

Evolutionary development. Certain Sphenophyta flourished as trees (*e.g., Calamites* species) during the coal-forming Carboniferous Period, but the earliest sphenophytes appeared as early as the Devonian. In its fossil history the division constituted a much larger portion of the flora of the Earth than it does at the present time.

Equisetum, which may also have been present during the Carboniferous, is perhaps one of the oldest living genera of vascular plants. The more primitive species have perennial, green shoots. The advanced species have annual, green, branched, vegetative shoots and often nongreen, unbranched, fertile shoots. Intermediate combinations of these features occur in some species.

Annotated classification. Botanists recognize four to six different orders in the division. Only one order, Equisetales, has both living and extinct species; all others comprise extinct sphenophytes. The latter are indicated by a dagger (†) in the listing below.

DIVISION SPHENOPHYTA (EQUISETOPHYTA; horsetails)
Extinct and living primitive, seedless, homosporous vascular plants with jointed, ribbed stems and whorls of leaves at regular intervals along the stem.

†Order Hyeniales (Protoarticulatae)
Extinct shrublike plants, with short, forked leaves in whorls; 1 family: Hyeniaceae (now placed with the Filicophyta—true ferns—by some paleobotanists).

†Order Pseudoborniales
One family, Pseudoborniaceae, with a single extinct species, *Pseudobornia ursina;* 15 to 20 metres (50 to 65 feet) tall.

†Order Sphenophyllales
Extinct scrambling or vinelike understory plants, 1 metre (3 feet) tall, with small, wedge-shape leaves; 2 families: Sphenophyllaceae and Cheirostrobaceae.

Order Equisetales
Two families: Calamitaceae, extinct tree horsetails; and Equisetaceae, herbaceous living horsetails and fossil allies with needlelike leaves in whorls along the stem; about 15 extant species in the genus *Equisetum* and several extinct species in the genus *Equisetites; Equisetum* is distributed predominantly in the Northern Hemisphere.

Critical appraisal. The extant genus *Equisetum* is a small remnant of a once diverse and dominant plant group. Although the genus includes two rather distinct groups, modern botanists recognize but a single genus.

Psilotophyta (whisk ferns)

The Psilotophyta are a division of spore-bearing vascular plants with the simplest structure known of any extant group. Psilotophytes have no true roots or leaves.

GENERAL FEATURES

Geographic distribution

The two genera, *Psilotum* (whisk ferns) and *Tmesipteris,* are terrestrial or epiphytic (living on other plant surfaces). *Psilotum,* an upright, green plant that looks like a leafless shrub about 30 centimetres (12 inches) high, is tropical and subtropical in distribution, reaching as far north as Florida. *Tmesipteris,* a hanging green epiphyte, is found in Australia, New Caledonia, New Zealand, the Philippines, and other islands of the South Pacific area. *Psilotum* is sometimes grown in greenhouses or even as a houseplant, but *Tmesipteris* has never been satisfactorily cultivated.

The conspicuous green plant, the sporophyte, consists of an aerial system and an underground stem (rhizome) system, both of which repeatedly fork dichotomously—*i.e.,* into two equal branches. No roots are present, the rhizome performing the functions of a root. In *Psilotum* the "leaves" are small, scalelike outgrowths without vascular tissue; in *Tmesipteris* they are larger, flattened structures, each with one unbranched midvein.

LIFE CYCLE

Psilotophytes alternate between two forms: gametophytes, which reproduce sexually, and sporophytes, which reproduce asexually. The psilotophytes are homosporous, the sporangia (spore cases) producing a single type of spore. After the spores are released by longitudinal splitting of the sporangium, they germinate to form the sex-cell-bearing plants—gametophytes. These plants are very small, measuring about 1 millimetre (0.04 inch) in diameter and a few millimetres in length. They may grow on trunks of trees or underground. Like the sporophyte, the gametophyte branches repeatedly. It is devoid of chlorophyll, however, and lives a saprophytic existence (*i.e.,* obtaining food from decaying organic matter), presumably aided by a fungus living within it.

The gametophytes are so similar to the underground rhizomes that they can be identified only by their gametangia—the sperm-producing antheridia and the egg-producing archegonia—which are scattered over the surface and are intermingled.

The first division of the zygote (fertilized egg) produces two cells. The outer cell continues to divide and forms the axis of the developing sporophyte. The inner cell gives rise to a multicellular "foot," which is in close contact with the gametophyte and presumably functions in the transfer of nutrients from the gametophyte to the young sporophyte.

FORM AND FUNCTION

Psilotophytes have a simple internal organization. In the rhizomes of both genera, the vascular tissue is in the form of a slender cylinder (protostele) occupying the centre of the stem. The upper branches of *Psilotum* are also protostelic. In the lower branches of *Psilotum* and in the stems of *Tmesipteris,* the vascular tissue forms a siphonostele, a cylinder surrounding nonvascular cells. The cells of the outer layers of the stem contain chloroplasts, and in *Psilotum* this region accounts for most of the photosynthesis.

Sporangia are three-lobed in *Psilotum* and two-lobed in *Tmesipteris.* The sporangia in *Psilotum* appear generally to be located in the axil of scalelike "leaves" but are actually on very short branches.

CYTOGENETICS

Chromosome numbers in the psilotophytes range from $x = 52$ to $4x = 208$. Hybridization is rare, the only reported hybrid (from Hawaii) being between the two species of *Psilotum.*

CLASSIFICATION

Annotated classification.

DIVISION PSILOTOPHYTA (whisk ferns)

The simplest of the primitive, seedless, homosporous plants, lacking roots; the upright stem or flattened "leaves" serve as photosynthetic organs and the horizontal stem serves to anchor the plant and to absorb nutrients.

Order Psilotales

One family, Psilotaceae, with 2 genera: *Psilotum,* a leafless, shrublike plant of the tropics and subtropics, with 2 species; and *Tmesipteris,* a hanging epiphyte with flattened leaflike structures, found in Oceania and the South Pacific area, with 7 species.

Critical appraisal. For many years this group was thought to be primitive in its simplicity and related to simple plants of Silurian and Devonian times (438 to 360 million years ago). However, the lack of an intervening fossil record and differences in morphology have led botanists to conclude that the Psilotophyta are unrelated to those early vascular plants. Whether the psilotophytes represent reduced lycophytes or are related to the ferns, such as the relatively undifferentiated *Stromatopteris,* is still in question. (E.M.G./J.T.Mi.)

BIBLIOGRAPHY. F.O. BOWER, *The Ferns (Filicales): Treated Comparatively with a View to Their Natural Classification,* vol. 1, *Analytical Examination of the Criteria of Comparison,* vol. 2, *The Eusporangiatae and Other Relatively Primitive Ferns,* and vol. 3, *The Leptosporangiate Ferns* (1923–28), is a classic work of comparative morphology and systematics that emphasizes the need, now being realized, for a broad spectrum of comparative data. A comprehensive summary of paleobotanical knowledge is provided in THOMAS N. TAYLOR, *Paleobotany: An Introduction to Fossil Plant Biology* (1981). The American Fern Society and the British Pteridological Society assemble the record of current research in the field in their publications *American Fern Journal* (quarterly), *Fiddlehead Forum* (bimonthly), *The Fern Gazette* (annual), and *Pteridologist* (annual).

The abundance and diversity of pteridophytes are the focus of HERMANN CHRIST, *Die Geographie der Farne* (1910), still an important broad treatment of fern distribution; JOHN T. MICKEL, *How to Know the Ferns and Fern Allies* (1979), the first manual to cover all of North America, with keys, brief descriptions, and illustrations; ROLLA M. TRYON and ALICE F. TRYON, *Ferns and Allied Plants* (1982), a good summary of the genera of tropical American pteridophytes with descriptions, maps, discussions, and many illustrations; JOHN T. MICKEL and JOSEPH M. BEITEL, *Pteridophyte Flora of Oaxaca, Mexico* (1988), the best illustrated and most comprehensive pteridophyte manual for Latin America; and R.E. HOLTTUM, *A Revised Flora of Malaya: An Illustrated Systematic Account of the Malayan Flora, Including Commonly Cultivated Plants,* vol. 2, *Ferns of Malaya* (1954), a well-illustrated enumeration and description of ferns that presents many of the author's ideas of systematic relationship.

Life cycle and habitats are discussed in A.F. DYER, *The Experimental Biology of Ferns* (1979), a series of essays on ecology, cytogenetics, reproduction, chemistry, and development; A.F. DYER and CHRISTOPHER N. PAGE (eds.), *Biology of Pteridophytes* (1985), a collection of symposium papers on a broad range of topics; F. GORDON FOSTER, *Ferns to Know and Grow,* 3rd rev. ed. (1984), a well-known book of horticulture with many helpful tips on cultivation; BARBARA JOE HOSHIZAKI, *Fern Growers Manual* (1975), a good introduction to horticulture with encyclopaedic information on the species in cultivation; and CHRISTOPHER N. PAGE, *Ferns: Their Habitats in the British and Irish Landscape* (1988), with excellent illustrations of habitats and ecology.

Studies of form and function include K.R. SPORNE, *The Morphology of Pteridophytes: The Structure of Ferns and Allied Plants,* 4th ed. (1975), a concise summary of ideas on fern structure; B.K. NAYAR and S. KAUR, "Gametophytes of Homosporous Ferns," *The Botanical Review* 37:295–396 (1971), a thorough summation of the knowledge of the haploid generation of ferns, with an extensive bibliography; JOHN T. MICKEL, *The Home Gardener's Book of Ferns* (1979), a useful compilation of information on fern morphology, diversity, and cultivation; and LENORE W. MAY, "The Economic Uses and Associated Folklore of Ferns and Fern Allies," *The Botanical Review* 44:491–528 (1978), a summary of the diverse uses to which ferns have been put.

For the origin and evolution of ferns and fern allies, see I. MANTON, *Problems of Cytology and Evolution in the Pteridophyta* (1950), a milestone in the biology of ferns containing, for the first time, accurate data on chromosomes in relation to evolution and systematics; RICHARD A. WHITE (ed.), "Taxonomic and Morphological Relationships of the Psilotaceae: A Symposium," *Brittonia* 29:1–68 (1977), a series of papers on structure, relationships, and fossil history; and J.D. LOVIS, "Evolutionary Patterns and Processes in Ferns," *Advances in Botanical Research* 4:229–439 (1977), an outstanding summary of the knowledge of fern phylogeny and classification. Also see appropriate sections of ROBERT F. SCAGEL *et al., An Evolutionary Survey of the Plant Kingdom* (1965); ERNEST M. GIFFORD and ADRIANCE S. FOSTER, *Morphology and Evolution of Vascular Plants,* 3rd ed. (1989); and DAVID W. BIERHORST, *Morphology of Vascular Plants* (1971), which provides detailed treatments of vascular plants together with theory and interpretation.

Nomenclature for the taxonomy of pteridophytes is provided in EDWIN BINGHAM COPELAND, *Genera Filicum: The Genera of Ferns* (1947), a valuable treatment of the classification and characteristics of ferns, containing many of the author's original correlations. Other works on classification include R.L. HAUKE, "The Taxonomy of Equisetum: An Overview," *New Botanist* 1:89–95 (1974); J.A. CRABBE, A.C. JERMY, and JOHN T. MICKEL, "A New Generic Sequence for the Pteridophyte Herbarium," *The Fern Gazette* 11:141–162 (1975), a list of pteridophyte genera in a phylogenetic sequence; and BENJAMIN ØLLGAARD, "A Revised Classification of the Lycopodiaceae s. lat.," *Opera Botanica* 92:153–178 (1987), a clear, detailed discussion of the taxonomic characters, genera, and species groups of the family, and *Index of the Lycopodiaceae* (1989), a listing of all the names, references, and type (original) specimens.

(W.H.Wa./E.M.G./J.T.Mi.)

Finland

An independent republic in northern Europe, Finland (Finnish: Suomi; in full Suomen Tasavalta, or Republic of Finland; Swedish: Finland, or Republiken Finland) is one of the world's most northern and geographically remote countries and is subject to a severe climate. It is bordered on the north by Norway, on the northwest by Sweden, on the southwest by the Gulf of Bothnia, on the south by the Gulf of Finland, and on the east by Russia. Its area is 130,559 square miles (338,145 square kilometres), of which the Åland Islands, an archipelago at the entrance to the Gulf of Bothnia, constitute 590 square miles. About one-third of the territory of Finland—most of the *lääni* (province) of Lapland—lies north of the Arctic Circle. The capital is Helsinki.

Finland was part of Sweden from the 12th century until 1809. It then was a Russian grand duchy until, following the Russian Revolution, the Finns declared independence on Dec. 6, 1917. Finland's area decreased by about one-tenth during the 1940s, when it ceded the Petsamo (Pechenga) area, which had been a corridor to the ice-free Arctic coast, and a large part of southeastern Karelia to the Soviet Union (ceded portions now in Russia).

Throughout the Cold War era, Finland maintained a carefully neutral political position, although a 1948 treaty with the Soviet Union (terminated 1991) required Finland to repel any attack on the Soviet Union carried out through Finnish territory by Germany or any of its allies. Since World War II, Finland has steadily increased its trading and cultural relations with other countries. Under a U.S.-Soviet agreement, Finland was admitted to the United Nations in 1955. Since 1955, Finland has sent representatives to the Nordic Council, which makes suggestions to member countries on the coordination of policies.

Finland's international activities became more widely known when the Conference on Security and Cooperation in Europe, which resulted in the creation of the Helsinki Accords, was held in that city in 1975. Finland has continued to have especially close ties with the other Scandinavian countries, sharing a free labour market and participating in various economic, cultural, and scientific projects. Finland became a member of the European Union (and its constituent European Community) in 1995.

This article is divided into the following sections:

Physical and human geography

THE LAND

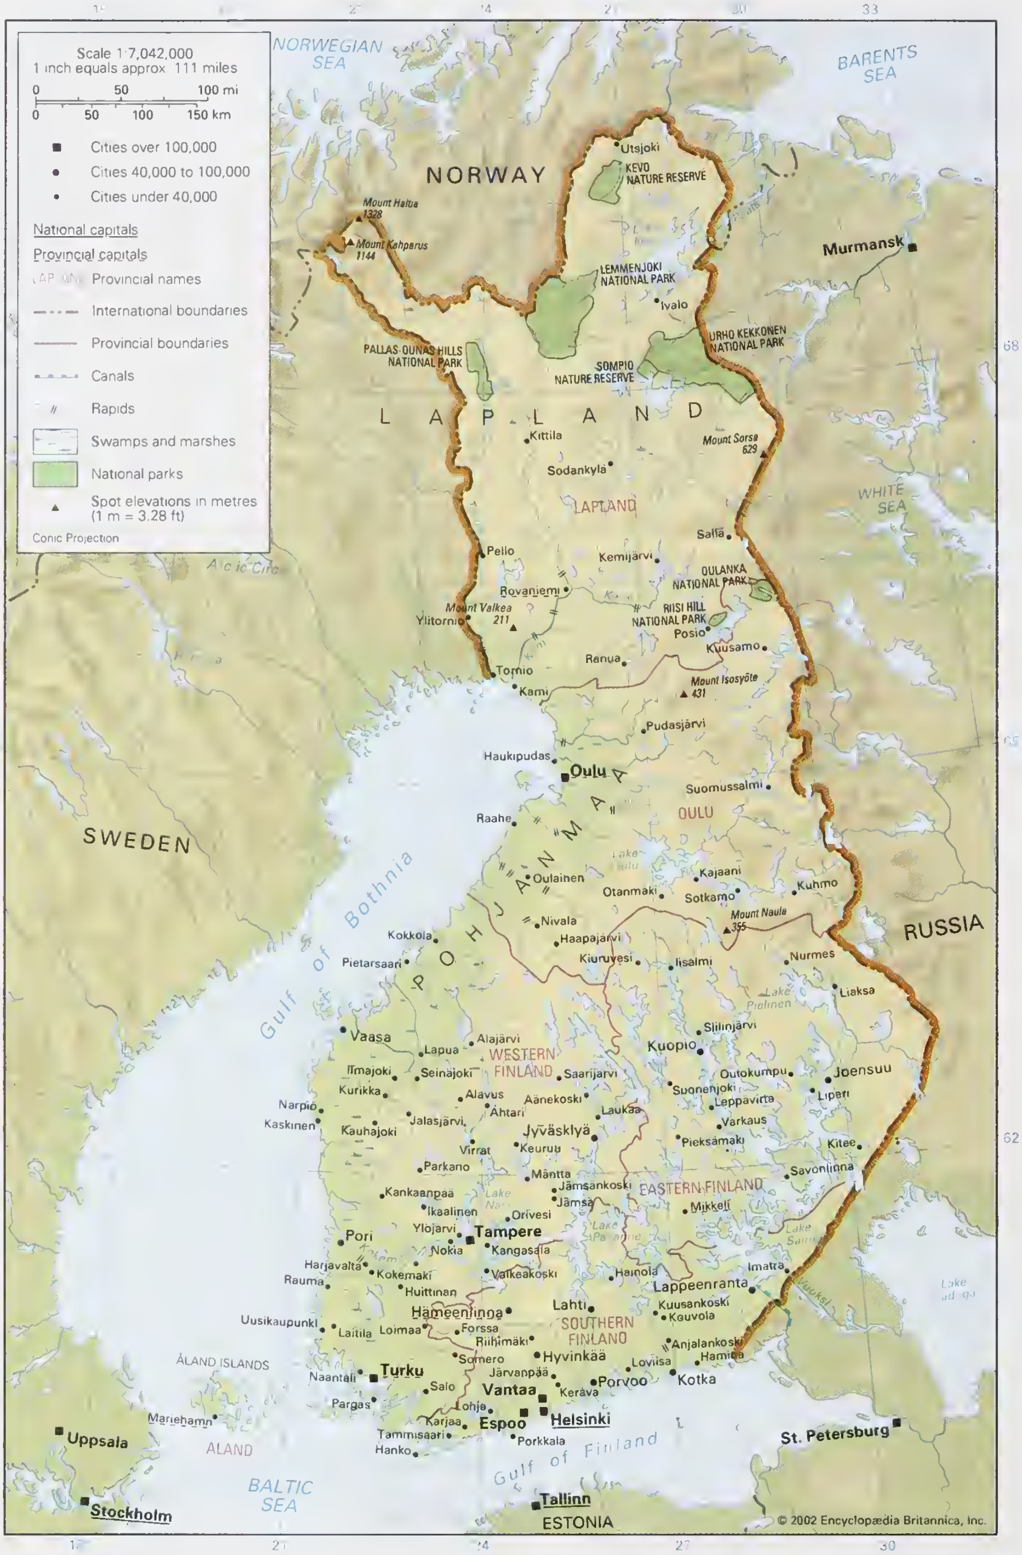
Relief. Finland is heavily forested and contains some 55,000 lakes, numerous rivers, and extensive areas of marshland; viewed from the air, Finland looks like an intricate blue and green jigsaw puzzle. Except in the northwest, relief features do not vary greatly, and travelers on the ground or on the water can rarely see beyond the trees in their immediate vicinity. The landscape nevertheless possesses a striking—if sometimes bleak—beauty.

Ancient underlying rocks

Finland's underlying structure is a huge worn-down shield composed of ancient rock, mainly granite, dating from Precambrian time (3,800,000,000 to 540,000,000 years ago). The land is low-lying in the southern part of the country and higher in the centre and the northeast, while the few mountainous regions are in the extreme northwest, adjacent to Finland's borders with Sweden and Norway. In this area there are several high peaks, including Mount Haltia, which, at 4,357 feet (1,328 metres), is Finland's highest mountain.

The coastline of Finland, some 2,760 miles (4,600 kilometres) in length, is extremely indented and dotted with thousands of islands. The greatest number of these are to be found in the southwest, in the Turun (Turku) archipelago, which merges with the Åland Islands in the west. The southern islands in the Gulf of Finland are mainly of low elevation, while those lying along the southwest coastline may rise to heights of more than 400 feet.

The relief of Finland was greatly affected by the Ice Age. The retreating continental glacier left the bedrock littered with morainic deposits in formations of eskers, remarkable winding ridges of stratified gravel and sand, running northwest to southeast. One of the biggest formations is the Salpausselkä ridges, three parallel ridges running across southern Finland in an arc pattern. The weight of the gla-



ciers, sometimes miles thick, depressed the Earth's crust by many hundreds of feet. As a consequence, areas that have been released from the weight of the ice sheets have risen and continue to rise, and Finland is still emerging from the sea. Land rise of some 0.4 inch (9 millimetres) annually in the narrow part of the Gulf of Bothnia is gradually turning the old sea bottom into dry land.

Drainage and soils. Finland's inland waters occupy almost 10 percent of the country's total area; there are 10 lakes of more than 100 square miles in area and tens of thousands of smaller ones. The largest lake, Saimaa, in the southeast, covers about 1,700 square miles. There are many other large lakes near it, including Päijänne and Pielinen, while Oulu is near Kajaani in central Finland, and Inari is in the extreme north. Away from coastal regions, many of Finland's rivers flow into the lakes, which are generally shallow—only three lakes are deeper than about 300 feet. Saimaa itself drains into the much larger Lake Ladoga in Russian territory via the Vuoksi (Vuoksa) River. Drainage from Finland's eastern uplands is through the lake system of Russian Karelia to the White Sea.

In the extreme north, the Paats River and its tributaries drain large areas into the Arctic. On the western coast, a series of rivers flow into the Gulf of Bothnia, including the

Tornio, which forms part of Finland's border with Sweden, and the Kemi, at 343 miles Finland's longest river. In the southwest the Kokemäen, one of Finland's largest rivers, flows out past the city of Pori (Björneborg). Other rivers flow southward into the Gulf of Finland.

Glacial influences in soil formation

Soils include those of the gravelly type found in the eskers, as well as extensive marine and lake postglacial deposits in the form of clays and silts, which provide the country's most fertile soils. The northern third of Finland has thick layers of peat. Such marshland still covers as much as 30 percent of the countryside. In the Åland Islands the soils are mainly clay and sand.

Climate. The part of Finland north of the Arctic Circle suffers extremely severe and prolonged winters. Temperatures can fall as low as −22° F (−30° C). In these latitudes the snow never melts from the north-facing mountain slopes, but in the short summer (Lapland has about two months of the midnight sun), from May to July, temperatures can reach as high as 80° F (27° C). Farther south the temperature extremes are slightly less marked. Annual precipitation, about one-third of which falls as sleet or snow, is about 25 inches in the south and a little less in the north. All Finnish waters are subject to some surface freezing during the winter.

Plant and animal life. Much of Finland is dominated by conifers, but in the extreme south there is a zone of deciduous trees comprising mainly birch, hazel, aspen, maple, elm, linden, and alder. The conifers are mainly pine and spruce. Pine extends to the extreme north, where it can be found among the dwarf arctic birch and pygmy willow. Lichens become increasingly common and varied in kind toward the north. In autumn the woods are rich in edible fungi. More than 1,000 species of flowering plants have been recorded. The sphagnum swamps, which are widespread in the northern tundra or bogland area, yield harvests of cloudberries, as well as plagues of mosquitoes.

Finland is relatively rich in wildlife. Seabirds, such as the black-backed gull and the arctic tern, nest in great numbers on the coastal islands; waterfowl, such as the black and white velvet scotcr duck, nest on inland lakes. Other birds include the Siberian jay, picd wagtail, and, in thc north, the eagle. Many birds migrate southward in winter. Native woodland animals include bear, clk, wolf, wolvcrinc, lynx, and Finnish clk. Wild reindccr havc almost disappeared; those remaining in the north are domesticatcd.

Salmon, trout, and *siika* (whitcfish) are rclativcly abundant in the northern rivcrs. Baltic herring is thc most common sea fish, while crayfish can be caught during the brief summer scason. Pikc, char, and perch arc also found.

The vegetation and wildlife of thc Åland Islands arc much like those of southern Finland.

Traditional regions. Thcre arc thrce principal rcgions in Finland: a coastal plain, an interior lake district, and an interior tract of higher land that rises to the fclls (*tunturi*) of Lapland. The coastal plain compriscs a narrow tract in the south, sloping from Salpausselkä to the Gulf of Finland, the southwest plains of the *lääni* (provincc) of Western Finland, and the broad western coastal lowlands of the region of Ostrobothnia (Pohjanmaa) facing the Gulf of Bothnia. The coastal region has thc most extcnsivc strctches of farmland; this region also has the longest continuous settlement and the largest number of urban ccntres. Associated with it are the offshore islands, which are most numerous in thc Turun archipelago off Turku (Åbo) on the southwest coast. Farther to the north in the Gulf of Bothnia, another group of islands lies off Vaasa (Vasa).

The lake district, with its inland archipelagoes, is the heart of Finland. It has been less subject to external influenccs than the coastal region, but since the end of World War II its population has increased, and it has becomc considerably industrialized. The northeast and north are the country's areas of expansion and development where many economic and social interests conflict, including, in the far north, the area of *saamelaisalue,* or Sami territory.

The Åland Islands is a region entirely distinct from Finland, not only because of its geographic separation but also because of its seagirt situation. The islands—whose inhabitants are almost entirely Swedish-speaking—are autono-

The Kokemäen River, with the town of Äetsä in the background, in southwestern Finland.

mous, have their own parliament, and fly their own flag. On the islands farming is a more usual occupation than fishing; there are mixed farms, as in the southwest of Finland, but fruit is also grown. Mariehamn (Maarianhamina) is the capital and only large town.

Settlement patterns. Increased industrialization in Finland has steadily raised the proportion of the population living in urban areas; by the late 20th century about three-fifths of the total population lived in cities and towns. Farms are most commonly located in the meadowland regions of the southwest, where the fertile land is suitable for mixed farming. In the north farmers usually concentrate on small dairy herds and forestry. In Finnish Lapland there is some nomadic life based mainly on the reindeer industry.

Major urban settlements

The major urban settlements are all in the southern third of the country, with a large number of cities and towns concentrated on the coast, either on the Gulf of Finland, as is the capital, Helsinki, or on the Gulf of Bothnia, as are Vaasa and Oulu (Uleåborg). The only town of any size in the north is Rovaniemi, capital of the *lääni* of Lapland. Helsinki is the largest city, with a population about three times that of Tampere (Tammerfors) and of Turku (Åbo), the country's capital until 1812. (C.F.S./I.Su.)

THE PEOPLE

Ethnic and linguistic composition. Excavations undertaken in 1996 have led to a radical reconsideration of how long people have inhabited Finland. Finds in a cave near Kristinestad have led some to suggest that habitation of Finland goes back at least 100,000 years. Ancestors of the Sami apparently were present in Finland by about 7000 BC. As other groups began to enter Finland some 3,000 years later, the proto-Sami probably retreated northward. Archaeological remains suggest that this second wave of settlers came from or had contact with what was to become Russia and also Scandinavia and central Europe. Peoples of Uralic (specifically Finno-Ugric) stock dominated two settlement areas. Those who entered southwestern Finland across the Gulf of Finland were the ancestors of the Tavastlanders, the people of southern and western Finland; those who entered from the southeast were the Karelians. Scandinavian peoples occupied the western coast and archipelagoes and the Åland Islands.

Finland has two national languages, Finnish and Swedish, and is officially bilingual. The Swedish-speaking population, found mainly in the coastal area in the south, southwest, and west and in the Åland Islands (where Swedish is the sole official language), is slowly declining and constitutes roughly 5 percent of the total. Nearly all of the remainder speak Finnish; the language is an important nationalist feature, although it is spoken in strong regional dialects. The Sami-speaking minority in the extreme north numbers some 6,000.

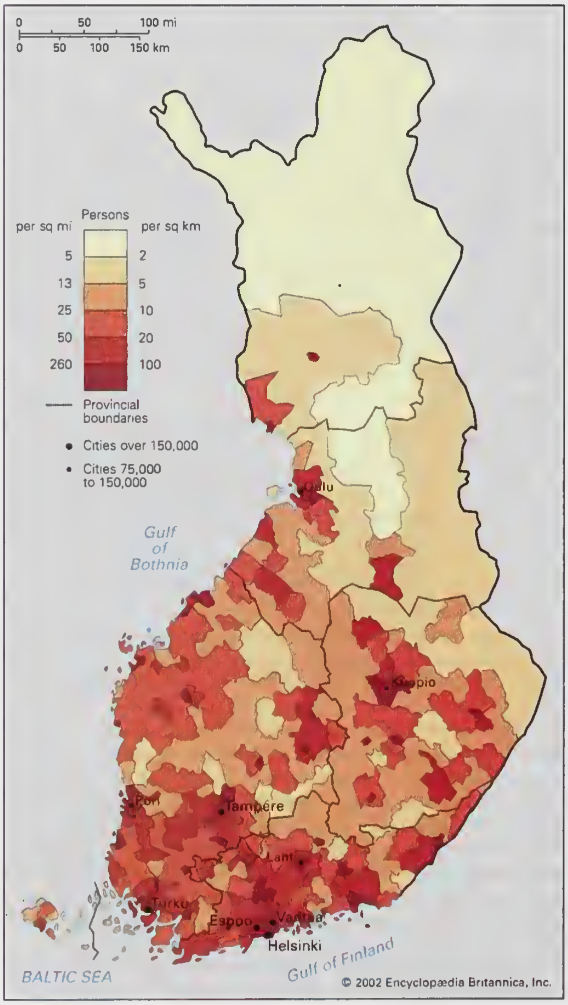
The Finnish Orthodox Church

Religions. Christianity entered Finland from both the west and the east as early as the 12th century. The great majority of the people belong to the Evangelical Lutheran Church, a national church whose bishops are nominated by the head of state. The archbishop has his see at Turku. A small number belong to the Greek Orthodox Church of Finland. The Finnish Orthodox Church was granted autonomy from Moscow in 1920, and in 1923 it was transferred to the jurisdiction of the patriarch of Constantinople. It has one archbishop, with his see at Kuopio. No other Christian denomination in Finland claims more than a few thousand members. Small Jewish and Muslim communities date from about 1850. More than one-tenth of the population have no church affiliation.

Demographic trends. Until the 1990s, emigration exceeded immigration, with Sweden being one of the most attractive destinations for Finnish emigrants. Following World War II, hundreds of thousands of Finns emigrated, while immigration was practically nil, owing to government restrictions. Since 1990, however, Finland has become a country of net immigration. Internal migration since the 1950s has been steadily toward the large towns and cities, most of which are in the south.

THE ECONOMY

Finland's economy is based primarily on private ownership and free enterprise; in some sectors, however, the gov-



Population density of Finland.

ernment exercises a monopoly or a leading role. After World War II, Finland was still only semi-industrialized, with a large part of the population engaged in agriculture, mining, and forestry. During the early postwar decades, primary production gave way to industrial development, which in turn yielded to a service- and information-oriented economy. The economy grew especially rapidly in the 1980s as the country exploited its strong trading relations with both eastern and western Europe. By the early 1990s, however, Finland was experiencing economic recession, reflecting both the collapse of the Soviet Union in 1991 and a general European economic slump. The economy began a slow recovery in the mid-1990s as Finland continued retooling its industry and refocused its trade primarily toward western Europe.

Unemployment was relatively low in Finland until 1991, when it increased rapidly. After peaking at nearly 20 percent of the workforce in 1994, the unemployment rate gradually began to decline again, falling in line with continental trends by the end of the 20th century. Finland's largest employer organization is the Confederation of Finnish Industry and Employers (formerly called the Finnish Employers' Confederation); the largest trade-union groups are the Central Organization of Finnish Trade Unions and the Confederation of Unions for Academic Professionals.

Finland has subscribed to the General Agreement on Tariffs and Trade since 1949 and to the Organisation for Economic Co-operation and Development since 1969. lt became first an associate (1961) and later a full member (1986) of the European Free Trade Association before leaving that organization to join the European Union in 1995; Finland also became a member of the constituent European Community (until 1993 called the European Economic Community), with which it had maintained a free-trade agreement since 1974. The Finnish government derives most of its revenue from income and value-added taxes. About two-fifths of the government's expenditures are for education and social scrvices.

Resources. Trees are Finland's most important natural resource. Some three-fourths of the total land area is forested, with pine, spruce, and birch bcing the prcdominant species. Government cultivation programs, among other measures, have prevented forest depletion; and acid rain, which has devastated forests in central Europe, has not had serious arboreal consequences in Finland.

Finnish peat deposits cover nearly one-third of the country, but only a small fraction of that land is suitable for large-scale peat production. Nearly all the production is used for fuel, with the remainder used in agriculture.

Ore deposits

A diversity of minerals occurs in the Precambrian bedrock, but mining output is modest, owing to the small size of the deposits and the low metal content of the ore. Most mines are located in the north. lron is the most important of the industrial metals. The main nonferrous metals are nickel and zinc. Chromium, cobalt, and copper are also economically important. Gold, silver, cadmium, and titanium are obtained as by-products. There is no naturally occurring coal or oil in Finland. Some mica is quarried, mostly for export.

Agriculture, forestry, and fishing. The declining role of agriculture in Finland's economy is indicated by the steadily decreasing proportion of the labour force working in agriculture. Much land has been taken out of agricultural production, and most farms consist of smallholdings. Finland has been self-supporting in basic foodstuffs since the early 1960s. Meat production roughly equals consumption, while egg and dairy output exceeds domestic needs. Grain production varies considerably; in general, bread grain (mainly wheat) is imported and fodder grain exported. The climate restricts grain farming to the southern and western regions of the country.

Animal husbandry in Finland traditionally concentrated on the raising of dairy cattle, but cuts were made after years of overproduction. As a result, the number of milk cows has declined. The number of horses also declined until the late 1970s but then became generally stable, with the subsequent increase in the number of Thoroughbred horses raised. The keeping of pigs, poultry, and reindeer also is important, while sheep farming and beekecping are of minor economic significance.

Finnish agriculture was heavily subsidized before the country entered the European Union, and after a period of negotiations it remains among the most heavily subsidized under the EU's Common Agricultural Policy. Finnish farmers rely heavily on direct payments based on the amount of land under cultivation. Those north of the 62nd parallel receive especially generous subsidies.

Forest resources

Despite the abundance of forest resources, the forest industry faces increasing production costs. The private owners of more than four-fifths of Finland's forests effectively control domestic timber prices; nonetheless, forest products (notably paper) are a major source of the country's export earnings.

Since World War II, fur farming has made great strides in Finland. Practically all furs are exported; Finland is the world's main producer of farm-raised foxes, and its mink furs also have a high reputation on international markets.

Commercial fishing has gradually become less significant to the economy. Among the fish in Finland's catch are salmon, sea and rainbow trout, whitefish, pike, and char. River pollution, as well as dams built for hydroelectric works, have adversely affected natural spawning habits, especially of salmon and sea trout, and Finland has established a large number of fish-breeding stations at which artificial spawning is induced. There is some trawling for Baltic herring, which also are taken in the winter by seine fishing (dragging nets under the ice) around the offshore islands. There are no longcr any professional hunters in Finland, but recreational hunting remains popular. Elk, waterfowl, and hare are the most common quarries.

Energy. Because of the cold climate and the structure of the nation's industry, Finland's per capita energy consumption ranks among the world's highest. Industries account for about half of total energy consumption, a much higher proportion than the Europcan avcragc. Domcstic energy sources meet only about one-third of Finland's total energy requirement, and all fossil fuels are imported.

Much of Finland's power comes from hydroelectric plants, but the low fall of water makes dam building nccessary. The loss in 1944 of Karelian hydroelectric rcsources turned attention to the north of the country, where plants were built on the Oulu and Kemi rivers. Thermal-generated powcr is also important. Finland's clectricity grids are linked with those of Sweden and Russia, and electricity is imported. lmatran Voima, the state-owned electric power company, began operation of a nuclear plant at Loviisa, east of Helsinki, in 1977; nuclear power now constitutes about one-third of all power generated.

Industry and technology. Finland's northern location imposes certain limitations on industrial activity; severe winter conditions make the costs of construction and heating high, and ice and snow are obstacles to transport. Industrialization in Finland began in the 1860s, but the pacc was slow, and early in the 20th century only some 10 percent of the population derived its livelihood from industry. lt was not until the mid-1960s that industry overtook farming and forestry together as an employer.

Forest products remain a vital sector of the Finnish economy. In the course of development, thc traditional manufactures of vegetable tar and pitch have given way to sawn timber and pulp and later to converted paper products, building materials, and furniture.

Development of heavy industry

Reparations payable to the Soviet Union after World War II, at first a burden, eventually proved a boon to Finland; their payment necessitated the development of heavy industry, which later found markets in western as well as eastern Europe. Metals and engineering now constitute the largest sector of Finnish industry. Finland holds a leading international position in the building of icebreakers, luxury liners, and other specialized ships and in the manufacture of paper-processing equipment. Finland's chemical industry has also grown rapidly. An important branch of the chemical industry is oil refining, the production capacity of which currently exceeds domestic oil requirements.

Textile factories are at Turku, Tampere, Vaasa, Forssa, and Hyvinkää. Helsinki is said to have Europe's largest porcelain factory, while Karhula (Kotka), Iittala, and Nuutajärvi are known internationally for glass. Leather and pewter goods, beer and vodka, and cement are among other important products. Liqueurs, soft drinks, and various sweets are made from cloudberries, currants, gooseberries, and lingonberries.

Finland embraced new technological developments with great enthusiasm. The telecommunications and information technology industry, led by firms such as Nokia, was crucial to the upswing in the Finnish economy of the late 1990s. By 1998 Finland had the largest per capita number of Internet users and mobile telephones in the world. Indeed, "Where are you?" has replaced "Hello" as the standard phone greeting.

Finance. From 1980 the Finnish financial market underwent rapid change. The state's role in the money market declined, and the economy grew increasingly market-oriented. Foreign banks were first allowed to operate in the early 1980s and to open branch offices in 1991.

The Bank of Finland (Suomen Pankki), established in 1811 and guaranteed and supervised by Parliament since 1868, is the country's central bank. The bank controls the circulation of the markka, the national currency established in 1860. Compared with other European countries, Finland has relatively little currency in circulation because Finns are very accustomed to banking electronically. Deposit banks are organized into three groups: commercial, cooperative, and savings. Securities trading is handled by the Helsinki Stock Exchange; foreign investors were first allowed to trade there in the early 1980s.

Trade. Because of Finland's relatively small domestic market, specialized production, and lack of energy sources, foreign trade is vital. The collapse of the Soviet Union and its loss as Finland's chief trading partner shook the Finnish economy. Trade with Russia, while still significant, has been overshadowed by that with the European Union. The chief trading partners are Germany, Sweden, and the United Kingdom. Although the traditional exports of paper and paper products and wood products remain important, heavy machinery and manufactured products now constitute the largest share of Finland's export trade. Imports consist mainly of raw materials for industrial use, consumer goods, and mineral fuels.

Transportation. Until the mid-20th century the problems posed to internal communications and transport by Finland's difficult terrain and weather conditions had hardly been tackled, and many communities remained isolated. External communications were mainly by sea, which, especially as a result of the period of Swedish rule, accounts for the series of well-developed ports on the Gulf of Bothnia and the Gulf of Finland.

Finland has a good network of highways and roads—of which about two-thirds are paved—but the lakes tend to make routes indirect in the southeast, while north of the Arctic Circle the roads are still few. Bridges and car ferries assist road travel in the lakeland areas and in the island archipelagoes. The bus system is highly developed throughout Finland and is widely utilized.

The railway system is much less adequate than that of the roads; the southwestern part of the country is the best-served area. The railways, which provide connections with Russia, are state-owned; about one-third of the rail lines are electrified. In 1982 Finland's first subway was inaugurated in Helsinki.

Navigable waterways

Finland has an extensive network of navigable waterways comprising lakes, rivers, and canals. Many thousands of miles of additional waterways are suitable for the flotage of felled timber, but truck and rail transport is rendering this practice obsolete in many areas. In 1963 the Soviet Union leased to Finland the Soviet end of the canal linking Lake Saimaa with the Gulf of Finland; it was opened in 1968. Most of Finland's overseas cargoes are carried in its own merchant marine. Finland has a passenger liner service, and car ferries operate to Denmark, Sweden, Germany, Estonia, Russia, and Poland.

In addition to the international air terminal near Helsinki, Finland has domestic airports, the most northerly of which is at Ivalo, at Lake Inari. Finnair, the national airline, offers internal and international service.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Finland adopted a republican constitution in 1919; it has been amended several times, notably in the mid-1990s. Legislative power rests in the unicameral Parliament (Eduskunta), which consists of 200 members elected for four years, and in the president, whose term is six years. Executive power is shared by the president and the Council of State, or cabinet, at whose meetings the president takes the chair. The president appoints the prime minister and the cabinet. A clause in the constitution stresses that government ministers are responsible to Parliament.

The role of the president

The president's six-year term of office and the possibility of reelection enhance his powers and provide the country with an important source of stability, in view of the frequent changes of government caused by the multiparty system. In cases of complete deadlock, the president can appoint a nonpolitical caretaker government. Government bills can be introduced into Parliament in the president's name; the president can refuse to sign a bill but must endorse it if it is passed in a subsequent Parliament. The president can dissolve Parliament, has certain decree-making powers, and is the head of the armed forces. The president also conducts foreign policy, but major treaties and matters of war must be validated by Parliament.

Regional and local government. Finland is divided into six *läänit* (provinces)—Åland (Ahvenamaa), Southern Finland (Etelä-Suomi), Eastern Finland (Itä-Suomi), Western Finland (Länsi-Suomi), Lapland (Lappi), and Oulu—each under a governor (*maaherra*) appointed by the president. The provincial governor is in charge of the provincial office (*lääninhallitus*) and the local sheriffs (*nimismies*). Åland, in addition to having a provincial governor, has its own local council, elected by universal suffrage, and a county executive board. The provinces of Finland are divided into communes, which may be rural or urban in character. Each commune council, elected for a four-year term, chooses its executive board. Communes are responsible for local health, education, and social services.

Political parties

Elections, political parties, and trade unions. Suffrage is universal for those over age 18. Presidential elections are direct. There are always more than two presidential candidates. Parliamentary elections are conducted by a system of proportional representation. There are 15 electoral districts. Proportional representation has led to a proliferation of political parties, including the Social Democratic Party, the Left-Wing Alliance (formed in 1990 from the People's Democratic League and the Finnish Communist Party), the National Coalition Party, and the Centre Party (or Finnish Centre; formerly the Agrarian Union). The People's Democratic League and its successor have been important parts of the government since World War II. The Swedish People's Party has become a distinct minority party, though it was formerly more important. The environmentalist Green Union displaced the Finnish Rural Party, a splinter of the former Agrarian Union.

Justice. The judiciary is independent of the legislature and executive; judges are removable only by judicial sentence. There are municipal and rural district courts, held in cities and towns by the chief judge (*oikeuspormestari*) and assistants and in the country by a judge and jurors. Appeal from these courts lies to courts of appeal in Helsinki, Turku, Vaasa, Kuopio, Kouvola, and Rovaniemi. The Supreme Court (Korkein oikeus), in Helsinki, appoints the district judges and those of the appeal courts. The chancellor of justice (*oikeuskansleri*), the supreme judicial authority, also acts as public prosecutor. Parliament appoints a solicitor general, who acts as an ombudsman. The Supreme Administrative Court (Korkein hallinto-oikeus) is the highest tribunal for appeals in administrative cases.

Armed forces. By the Treaty of Paris (1947), Finland was permitted to maintain an army of 34,400 men, an air force of 3,000 men and 60 combat aircraft, and a navy of 4,500 men with ships totaling 10,000 tons. According to the treaty, bombers, submarines, and missiles, as well as nuclear weapons, were forbidden, but in a 1963 agreement Finland was allowed to acquire certain classes of defensive missiles. All male citizens age 17 to 60 are liable for military service, but civil service duty is available to conscientious objectors. (C.F.S./I.Su./S.R.L.)

Education. School attendance in Finland is compulsory beginning at the age of seven. The national and local governments support the schools, and tuition is free. The introduction of a new nine-year comprehensive school system, consisting of a six-year primary stage and a three-year secondary stage, was completed during the 1970s. The English language is taught beginning in the third year, but students can also have the choice of studying other foreign languages. Finland's nine-year comprehensive school system is followed by either a three-year upper secondary school or a vocational school.

University of Helsinki

The only higher education institutions in Finland that were founded before the country achieved independence are the University of Helsinki, founded at Turku in 1640 and transferred to Helsinki in 1828, and the Helsinki University of Technology, founded in 1849. There are also universities located at Jyväskylä, Oulu, Joensuu, Kuopio, and Tampere and two (one Finnish- and one Swedish-language) universities located at Turku. Other institutions of higher education include several technical universities and schools of commerce, as well as a college of veterinary medicine. State aid for higher education is available.

Health and welfare. Social security in Finland comprises a system of pensions and care for the aged, unemployment benefits, health care, and family welfare plans. The state pays disability pensions and old-age pensions to persons 65 years of age and older. The cost of these pensions is met from premiums originally paid by the beneficiaries and payments by employers and by the central and local governments. The Central Pensions Security Institute administers an additional earnings-related old-age pension, which is also available to farmers and other self-employed people. The National Board of Social Welfare provides care and attention for the elderly, including recreational centres to provide social amenities. Other social programs include unemployment benefits and compensation for industrial accidents, maternity benefits, and family allowances for all children under 16.

Health centres, run by local authorities, supply free medical treatment, but there are also licensed private practitioners. The country is divided into hospital districts, each with a central hospital maintained by intermunicipal corporations. There are also smaller regional hospitals and a few private hospitals. The patient pays only a small daily hospital charge. In addition the state reimburses an average of 60 percent of the patient's expenditures on drugs. The Finns are known as a healthy and vigorous people and are characterized by their penchant for sauna baths. Indeed, the life expectancy for Finns is among the highest in the world.

The National Board of Housing addresses problems of housing supply and development. There is a general housing shortage, acute in the towns and especially so in Helsinki. Low-income families are eligible to obtain state-subsidized flats, and government loans for mortgages are also obtainable. Brick and concrete are surpassing wood as building materials, although many Finnish families have vacation cottages, typically modest lakeside dwellings of traditional log or timber construction.

The police authorities are subordinated by the Ministry of the Interior. The cities pay to the state a part of the expenses for local police forces.

CULTURAL LIFE

The *Kalevala*, Finland's national epic

The arts. Finland's national epic, the *Kalevala*, compiled in the 19th century by the scholar Elias Lönnrot from old Finnish ballads, lyrics, and incantations, played a vital part in fostering Finnish national consciousness and pride. Indeed, the development of almost all Finland's cultural institutions and activities has been involved with and motivated by nationalist enthusiasm. This theme can be demonstrated in the growth and development of Finnish theatre and opera, in writing and music, in art and architecture, and also in sport. The festivals of various arts, held annually at places such as Helsinki, Vaasa, and Kaustinen, and the postwar proliferation of museums in Finland show an awareness of the individuality and importance of Finland's contribution to world culture. Savonlinna, in particular, is celebrated for its annual opera festivals.

Theatre, opera, and music. Drama in Finland is truly popular in the sense that vast numbers act in, as well as watch, theatrical productions. Besides the approximately 40 theatre companies in which all the actors are professionals, there are some in which a few professionals or even the producer alone are supplemented by amateur performers. There are amateur theatrical companies in almost every commune.

The country's most important theatre is the National Theatre of Finland, established in 1872 with Kaarlo Bergbom as producer and manager; its granite building in Helsinki was built in 1902. There are also several other municipal theatres. One of the most exciting in the country is the Pyynikki Open Air Theatre of Tampere, the revolving auditorium of which can be moved to face any of the natural sets. There are innumerable institutions connected with the theatre in Finland, including the Central Federation of Finnish Theatrical Organizations. There is a wide repertory of Finnish as well as international plays. The Finnish theatre receives some degree of government assistance.

Finnish opera

The main centre for opera is the Finnish National Opera in Helsinki; the Savonlinna Opera Festival takes place every summer. The international success of Finnish singers such as Taru Valjakka, Jorma Hynninen, and Martti Talvela has added to the continuing national enthusiasm for opera. Several new Finnish operas, including *The Last Temptations* by Joonas Kokkonen and *The Horseman* by Aulis Sallinen, have received successful premieres. Sallinen's *The King Goes Forth to France* (1984) was commissioned jointly by The Royal Opera Covent Garden, the British Broadcasting Corporation, and the Savonlinna Opera Festival.

The dominant figure in Finnish music during the first half of the 20th century was Jean Sibelius, the country's best-known composer, who brought Finnish music into the repertoire of concert halls worldwide. The centre for higher musical studies in Helsinki was renamed the Sibelius Academy. The city is also the location of the Helsinki Philharmonic Orchestra and the Finnish Radio Symphony Orchestra. The Sibelius violin competition and Mirjam Helin song competition are held there every five years. There are annual music festivals in Helsinki and several other cities. Internationally known Finnish conductors include Paavo Berglund, Okko Kamu, and Esa-Pekka Salonen.

Literature. Epic prose has played and continues to play an important role in Finnish literature. *Seitsemän veljestä* (1870; *Seven Brothers*) by Aleksis Kivi is considered to be the first novel written in Finnish. Other early leading prose writers included Frans Eemil Sillanpää, the winner of the Nobel Prize for Literature in 1939. Although Mika Waltari represented newer trends in literature, it was his historical novels, among them *Sinuhe, egyptiläinen* (1945; *The Egyptian*), that brought him fame. Väinö Linna, a leading postwar writer, became known for his war novel *Tuntematon sotilas* (1954; *The Unknown Soldier*) and for the trilogy *Täällä Pohjantähden alla* (1959–62; "Here Under the North Star"). Other novelists have written in shorter forms, but the broad epic has remained popular, particularly among writers describing the contradictions in Finnish life from the turn of the century to modern times.

Literature written in Swedish has had a long tradition in Finland. Among 19th-century writers, Johan Ludvig Runeberg, the national poet, and Zacharias Topelius played leading roles. Later 20th-century poets such as Edith Södergran had a strong influence on the modern poetry of both Finland and Scandinavia. The Swedish language continues to be used in Finnish literature.

Art, architecture, and design. From the time that the *Kalevala* inspired the paintings of Akseli Gallén-Kallela, there has been a distinctive school of Finnish painters, but the Finnish artistic genius has been continually drawn to three-dimensional work. Sculpture is important, highly abstract, and experimental; Eila Hiltanen's monument to Sibelius in Helsinki is composed of chrome, metal, and steel tubes.

Modern Finnish architecture is among the most imaginative and exciting in the world. Its development was closely allied to the nationalist movement, and among its pioneers were Eliel Saarinen, whose work is exemplified by the National Museum and the Helsinki railway station, and Lars Sonck, whose churches in Helsinki and Tampere are particularly notable.

Modern architecture

In the 20th century the idea of functionalism was developed by Gustaf Strengell. In the 1920s Alvar Aalto and Eric Bryggman began experimenting with regional variations on the International Style. Among the most striking examples of Aalto's work are the Paimio Sanatorium, the library at Viipuri, and Finlandia House, a concert and congress hall in Helsinki. There is general experimentation, using concrete and metals, in Finnish industrial buildings and flats and in environmental design, as at the garden town of Tapiola outside Helsinki. The new generation of architects has continued these standards. Outside Finland, Viljo Rewell has received acclaim for his Toronto City Hall in Canada.

Finnish design—especially in glass, porcelain, and textiles—became internationally known during the postwar period. Factories like the well-known Arabia in Helsinki have given artists a free hand to develop their ideas and skills. Tapio Wirkkala and Timo Sarpaneva in glassware, Marjatta Metsovaara in textiles, and Dora Ljung in *ryijy* rugs are among the best-known designers.

Press and broadcasting. Freedom of the press is guaranteed by the 1919 constitution and the Freedom of the Press Act (also 1919); both contain provisions safeguarding editorial rights and outlining press responsibilities. The Supreme Court can suppress publications under certain circumstances, but in general there are few restrictions apart from those governing libel and copyright.

Newspaper publication began in Finland in 1771, and the *Åbo Underrättelser,* published in Swedish, has been in operation since 1824. Finland now has more than 200 regular newspapers, including some 50 dailies, most of which are independently owned and operated. A small number of publications are, however, owned by political parties or trade unions. The national Finnish News Agency (Oy Suomen Tietotoimisto; founded 1887) is independent and owned by the press.

The state-run Finnish Broadcasting Company (Oy Yleisradio Ab [YLE]; established 1926) has no legal monopoly, though no private radio broadcasting companies were allowed until 1985. YLE operates two nationwide television networks and leases a third to a private commercial company; in addition, YLE maintains a fourth channel that broadcasts programs from Swedish television to the coastal areas.

Cross-country skiing

Recreation. In Finland the basic national sport—which originally was a necessary means of winter transportation—is cross-country skiing. Nationalism also encouraged the development of special proficiency, which was fostered by ski fairs and competitions held at Oulu beginning in the late 1890s. An interest in other athletics developed from the time that the Finns took part in the interim Olympic Games held in Athens in 1906. Finns have excelled in Olympic track and field as well as winter sports. Paavo Nurmi, who won six gold medals in Olympic middle- and long-distance running events in the 1920s, became a national hero. Other popular sports are waterskiing, riding, fishing, shooting, ice hockey, and *pesäpallo,* a Finnish version of baseball. (C.F.S./I.Su.)

For statistical data on the land and people of Finland, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

EARLIEST PEOPLES

The first people arrived in Finland about 9,000 years ago. They probably represented several groups and tribes, including the ancestors of the present Sami. Lured by the plenitude of game, particularly fur-bearing animals and fish, they followed the melting ice northward. The first people perhaps came to hunt only for the summer, but gradually more and more of them stayed over the winter. Apparently berries played a significant role in their diet.

Another group probably arrived some 3,000 years later from the southeast. They possibly spoke a Finno-Ugric language and may have been related to the ancestors of the present Finns, if they were not actually of the same group. Other peoples—including the ancestors of the Tavastians—followed from the southwest and central Europe, eventually adopting the Finno-Ugric tongue.

During the 1st millennium BC several more groups arrived, among them the ancestors of the present Finns. The nomadic Sami, who had been scattered over the greater part of Finland, withdrew to the north. Most other groups intermarried and assimilated with the newcomers, and settlement spread across the south of Finland. The population was still extremely sparse, but three loose unities seem to have crystallized: the Finns proper, the Tavastians, and the Karelians. These each had their own chiefs, and they waged war on one another.

Trade colonies

Even before the beginning of the Viking Age (8th–11th century AD), Swedes had settled on the southwestern coast. During the Viking Age, Finland lay along the northern boundary of the trade routes to Russia, and the inhabitants of the area served as suppliers of furs. The Finns apparently did not take part in the Viking expeditions. The end of the Viking Age was a time of unrest in Finland, and Swedish and Danish raids were made on the area, where Russians and Germans also traded.

COMPETITION FOR TRADE AND CONVERTS

From the 12th century, Finland became a battleground between Russia and Sweden. The economic rivalry of the powers in the Baltic was turned into a religious rivalry, and the Swedish expeditions took on the character of crusades. Finland is mentioned together with Estonia in a list of Swedish provinces drawn up for the pope in 1120, apparently as a Swedish missionary area. The first crusade, according to tradition, was undertaken in about 1157 by King Erik, who was accompanied by an English bishop named Henry. Henry remained in Finland to organize the affairs of the church and was murdered by a Finnish yeoman; by the end of the 12th century, he was revered as a saint, and he later became Finland's patron. In a papal bull (*c.* 1172), the Swedes were advised to force the Finns into submission by permanently manning the Finnish fortresses in order to protect the Christianization effort from attacks from the east.

By the end of the 12th century, competition for influence in the Gulf of Finland had intensified: German traders had regular contacts with Novgorod via Gotland, and Denmark tried to establish bases on the gulf. The Danes reportedly invaded Finland in 1191 and again in 1202; in 1209 the pope authorized the archbishop of Lund to appoint a minister stationed in Finland. The Swedish king counterattacked, and in 1216 he received confirmation from the pope of his title to the lands won by himself and his predecessors from the heathens. He was also authorized to establish a seat for one or two bishops in the Finnish missionary territory. In eastern Finland the Russian church attempted to win converts, and in 1227 Duke Jaroslav undertook a program of forced baptisms, designed to tie Karelia closer to Novgorod. In response the pope placed Finland under apostolic protection and invoked a commercial blockade against Russia (1229). A large force, led by Birger, a Swedish jarl (a noble ranking immediately below the king), and including Swedes, Finns, and crusaders from various countries, was defeated in 1240 by a duke of Novgorod, and the advance of Western Christendom into Russia was halted, while the religious division of Finland was sealed, with the Karelians in the Eastern sphere. The bishop of Finland, Thomas, resigned in 1245, and the mission territory was left without leadership until 1249, when the Dominicans founded a monastery in Turku.

FINLAND UNDER SWEDISH RULE

Birger Jarl's conquest

Birger Jarl decided that a full effort was necessary to bring Finland into the Swedish sphere; in 1249 he led an expedition to Tavastia (now Häme), an area already Christianized. Birger built a fortress in Tavastia and some fortifications along the northern coast of the Gulf of Finland, where Swedish settlement on a mass scale began.

Swedes also moved to the eastern coast of the Gulf of Bothnia. In 1293 Torgils Knutsson launched an expedition in an attempt to conquer all of Karelia and built a fortress in Viipuri. The war lasted until 1323, when the Treaty of Pähkinäsaari (Nöteborg; now Petrokrepost) drew the boundary between the Russian and Swedish spheres of influence in a vague line from the eastern part of the Gulf of Finland through the middle of Karelia northwest to the Gulf of Bothnia, and the crusades were ended, with Finland a part of the Swedish realm.

The Swedes began to administer Finland in accordance with Swedish traditions. Castles were built and taxes were collected, mainly in furs and, later, in grain, butter, and money. During the early Middle Ages, Finland was often given to members of the royal family as a duchy. Two new estates, the clergy and the nobility, evolved, with the nobility increased by transplantation from Sweden and the clergy containing a large native element. The first native bishop was appointed in 1291.

Union with Sweden. In 1362 King Haakon of Sweden established the right of the Finns to participate in royal elections and the equal status of Finland with the other parts of the kingdom. Several years later Haakon was overthrown and Albert of Mecklenburg was crowned. Albert was unpopular with the Finns, and by 1374 a Swedish nobleman, Bo Jonsson Grip, had gained title to all of Finland. Grip died in 1386, and Finland soon after became part of the Kalmar Union. (H.En./M.I.He.)

The 15th, 16th, and 17th centuries. Under Swedish sovereignty the Finnish tribes gradually developed a sense of unity, which was encouraged by the bishops of Turku. Study in universities brought Finnish scholars into direct touch with the cultural centres of Europe, and Mikael Agricola (*c.* 1510–57), the creator of the Finnish literary language, brought the Lutheran faith from Germany. As part of medieval Sweden, Finland was drawn into the many wars and domestic battles of the Swedish nobility. In 1581 King John III raised Finland to the level of a grand duchy to irritate his Russian rival, Tsar Ivan IV the Terrible. Dispute over the Swedish crown, combined with quarrels over social conditions, foreign policy, and religion (Roman Catholic versus Lutheran), led to the last peasant revolt in Europe, the so-called Club War, in 1596–97. The hopes of the Finnish peasants were crushed, and, even when Charles IX, whom the peasants had supported, became king (1604–11), the social conditions did not improve. In the course of the administrative reforms of Gustav II Adolf (1611–32), Finland became an integral part of the kingdom, and the educated classes thereafter came increasingly to speak Swedish.

Peace of Täysinä

On its eastern frontier Finland was harassed by constant warfare, and the danger became more serious when Novgorod, at the end of the medieval period, was succeeded by a more powerful neighbour, the Grand Duchy of Moscow. In 1595, however, by the Peace of Täysinä, the existing de facto boundary, up to the Arctic Ocean, was granted official recognition by the Russians. By the Peace of Stolbovo (Stolbova; 1617), Russia ceded Ingermanland and part of Karelia to the kingdom of Sweden-Finland. The population of the ceded territories was of the Greek Orthodox faith, and when the Swedish government began forceful conversion to Lutheranism many fled to Russia and were replaced by Lutheran Finns. After Stolbovo, Sweden found new outlets for expansion in the south and west and developed into one of the leading powers of Europe. Though Finnish conscripts played their part in making Sweden a great power, the role of Finland in the kingdom steadily decreased in importance.

The 18th century. In Charles XII's reign, Sweden lost its position as a great power. During the Great Northern War, Russians occupied Finland for eight years (1713–21), and, under the Peace of Uusikaupunki (Nystad) in 1721, Sweden had to cede the southeastern part of Finland with Viipuri as well as the Baltic provinces. Sweden's capacity to defend Finland had weakened, and the years of hostile occupation had given the Finns a permanent feeling of insecurity.

In the course of the next Russo-Swedish War (1741–43), the Russian empress Elizabeth declared to the Finnish people her intention of making Finland a separate state under Russian suzerainty, but she failed to follow up the idea and at the peace settlement of Turku in 1743 contented herself with annexing a piece of Finland. Meanwhile, however, her original idea had found favour with some Finns. During the next bout of hostilities (1788–90), a number of Finnish officers involved themselves in the activities of Göran Magnus Sprengtporten, a Finnish colonel who had fled to Russia and who wanted to detach Finland from Sweden; this movement won little general support, however.

AUTONOMOUS GRAND DUCHY

As a part of the Swedish monarchy, Finland had been accorded practically no institutions of its own, but from the middle of the 18th century the majority of officials and intellectuals were of Finnish origin. In those circles there was a growing feeling that Finland had to bear the cost of Swedish extravagances in foreign policy. The feeling was not unfounded. Swedish strategic directives of 1785 implied that, in case of Russian attack, Swedish forces should retire from the frontier, leaving Finnish detachments behind, and that under extreme danger the whole of Finland should be evacuated. This strategy was put into effect in 1808–09. Even the treachery of the Anjala association in 1788 was repeated in 1808, when Sveaborg (Viapori; now Suomenlinna) near Helsinki capitulated to the Russians. In 1809 the Finns themselves had to carry the responsibility of coming to terms with Russia. Alexander I offered to recognize constitutional developments in Finland and to give it autonomy as a grand duchy under his throne. (G.Sa./M.I.He.)

The era of bureaucracy. The political framework of Finland under Russia was laid down by the Porvoo (Borgå) Diet in 1809. Finland was still formally a part of Sweden until the peace treaty of Hamina (Fredrikshamn) later that year, but most of the Finnish leaders had already grown tired of Swedish control and wanted to acquire as much self-government as possible under Russian protection. In Porvoo, Finland as a whole was for the first time established as a united political entity—a nation.

In recognition of Finnish autonomy, Alexander I promised to respect the religion and fundamental laws of Finland, as well as the privileges and rights of the inhabitants (that is to say, the Swedish constitution of 1772 as amended in 1789, by which the regent alone had the executive power while the consent of the Diet was required for legislation and the imposition of new taxes). The grand duke (the emperor) was not obliged to convene the Diet at regular intervals, and as a result it did not meet until 1863. From 1809 to 1863 Finland was ruled by a bureaucracy chosen by the Russian emperor, who was represented in Finland by a governor-general. Some holders of this office were Finns in the early period of the Russian regime. The highest administrative organ during the period was the Senate, which consisted of a judicial department and an economic department. The former was the country's supreme court, while the latter became a sort of ministry. A ministerial state secretary in St. Petersburg represented Finnish affairs to the emperor.

Reforms of the Russian period. For most Finns the "era of bureaucracy" was a time of growing prosperity, favourable economic conditions, and no warfare except during the Crimean War (in Finland, the War of Åland). At that time an Anglo-French fleet attacked the Åland Islands, the fortress of Viapori in Helsinki, and some coastal towns on the Gulf of Bothnia. On its separation from Sweden in accordance with the Treaty of Hamina, Finland had a population of more than 900,000. As elsewhere in the Nordic countries, population growth was rapid, and by 1908 the figure had exceeded 2,000,000. Most of the population lived off the land. Manufacture of wooden articles, export of timber, shipbuilding, and merchant shipping were practiced in the small coastal towns.

Despite the strongly authoritarian and bureaucratic form of government, a number of important reforms were implemented. In 1812 the Emperor was induced to restore those areas of Finnish territory that Sweden had ceded to Russia by the treaties of Uusikaupunki (1721) and Turku

(1743). Furthermore, in 1812 Helsinki was chosen as the capital, and the monumental buildings in its centre stem from this period. But the vast rural population and purely agrarian structure prevented the spread of liberal and national ideas to any great extent during the first part of the 19th century.

The Finnish language ordinance

The language problem. The reaction reached its climax with the Finnish language ordinance of 1850, which forbade the publication in Finnish of books other than those that aimed at religious edification or economic benefit. Since Finnish was the only language understood by the majority of the population, the ordinance smacked of an attempt to maintain class differences and was well suited to preserve the existing bureaucracy.

As late as the mid-19th century, Swedish was the only language allowed within the Finnish administration. There was an almost total lack of literature in Finnish, and teaching at both the secondary and university levels was in Swedish. The division between the two languages became not only of national and cultural significance but also a social distinction. This is one of the reasons why the language controversy in Finland created such bitterness. To begin with, the advocates of a Finnish-speaking Finland, or Fennomans, were successful. By recording folk songs and writings, a Finnish literature was developed during the latter part of the 19th century. The first purely Finnish-speaking grammar school appeared in 1858. In 1863 Alexander II (ruled 1855–81) issued a decree stating that, after a 20-year interim period, Finnish was to be placed on an equal footing with Swedish in the administration and in the law courts, as far as their relations with the public were concerned. Swedish, however, remained the language of internal administration, and it was not until 1902 that Swedish and Finnish were placed on an equal footing as official languages.

Reform of the Diet and other reforms. During the reign of Alexander II other reforms were begun. The most important was his convening of the Diet in 1863, and the promulgation of a new act in 1869 providing that it thereafter should be convened regularly. The next great reform period came after the Russian defeat in the war against Japan (1904–05).

Until the 1890s, Russia respected Finland's special position within the Russian Empire in all essentials. In addition to the Diet ordinance of 1869, the country acquired its own monetary system (1865), and a law on conscription, which laid the foundations for the Finnish Army, was passed in 1878.

THE STRUGGLE FOR INDEPENDENCE

Nationalism had already begun to raise its head in Russia before the end of Alexander II's reign, but his strong-minded successor, Alexander III, who had a personal liking for Finland, was able to resist the demands of the Russian nationalists for the abolition of Finnish autonomy and the absorption of the Finns into the Russian nation. The emergence of a united Germany south of the Baltic also worried the Russians, who wanted to secure the loyalty of Finland. Russian jurists took the line that, though Alexander I in virtue of his supreme powers had granted Finland autonomous rights, any Russian emperor exercising the same supreme powers was entitled to take them back whenever he wished. Applying this principle, Nicholas II issued a manifesto on Feb. 15, 1899, according to which he was entitled, without the Finnish Diet's consent, to enact laws enforceable in Finland if such laws affected Russian interests. Direct attempts at Russification were then made. The gradual imposition of Russian as the third official language was ordered in 1900, and in 1901 it was decreed that Finns should serve in Russian units and that Finland's own army should be disbanded. Increasing executive power was conferred on the ultranationalist governor-general, General Nikolay Bobrikov. Faced with this situation, two opposing factions crystallized out of Finland's political parties: the Constitutionalists (the Swedish Party and the Young Finnish Party), who demanded that no one observe the illegal enactments; and the Compliers (the Old Finnish Party), who were ready to give way in everything that did not, in their opinion, affect Finland's vital interest. The Constitutionalists were dismissed from their offices and their leaders were exiled. Young men of Constitutionalist views refused to report for service when called, and at last the Emperor had to give in: the Finnish Army remained disbanded, but no Finns were drafted into the Russian Army. A more extreme group, known as the Activists, was prepared to endorse even acts of violence, and Bobrikov was assassinated by them.

Resistance and reform. Further opposition came from the Labour Party, which was founded in 1899 and which in 1903 adopted Marxist tenets, changing its name to the Social Democratic Party. Unwilling to compromise with tsarist Russia, the party was developing along revolutionary lines. When the Constitutionalists, availing themselves of Russia's momentary weakness, combined with the Social Democrats to organize a national strike, the Emperor restored the situation that had prevailed before 1899 (Nov. 4, 1905)—but not for long. Another result of the strike was a complete reform of the parliamentary system (July 20, 1906). This had been the Social Democrats' most insistent demand. The old four-chamber Diet was changed to a unicameral Parliament elected by equal and universal suffrage. Thus, from having one of Europe's most unrepresentative political systems, Finland had, at one stroke, acquired the most modern. The parliamentary reform polarized the political factions, and the ground was laid for the modern party system. The introduction of universal and equal suffrage meant that the farmers and workers potentially commanded a great majority. The Social Democrats became the largest party in Parliament, obtaining 80 seats out of 200 in the very first elections (1907). Nevertheless, the importance of Parliament remained very small, as it was constantly being dissolved by the Emperor; thus the assault on Finnish autonomy soon began afresh. The Constitutionalists resigned from the government, and the Compliers soon followed their example, since even in their opinion the extreme limit had been overstepped. In the end an illegal Senate composed of Russians was formed. In 1910 the responsibility for all important legislation was transferred to the Russian Duma.

Effect of the Russian Revolution

Return to autonomy. During World War I the Finnish liberation movement sought support from Germany, and a number of young volunteers received military training and formed the Jägar Battalion. After the Russian Revolution in March 1917, Finland obtained its autonomy again, and a Senate, or coalition government, assumed rule of the country. By a law of July 1917 it was decided that all the authority previously wielded by the emperor (apart from defense and foreign policy) should be exercised by the Finnish Parliament. After Russia was taken over by the Bolsheviks in November 1917 Parliament issued a declaration of independence for Finland on Dec. 6, 1917, which was recognized by Lenin and his government on the last day of the year.

EARLY INDEPENDENCE

Although the liberation from Russia occurred peacefully, Finland was unable to avert a violent internal conflict. After the revolutionaries had won control of the Social Democratic Party, they went into action and on Jan. 28, 1918, seized Helsinki and the larger industrial towns in southern Finland. The right-wing government led by the Conservative Pehr Evind Svinhufvud fled to the western part of the country, where a counterattack was organized under the leadership of General Carl Gustaf Mannerheim. At the beginning of April the White Army under his command won the Battle of Tampere. German troops also came to the aid of the White government and captured Helsinki; by May the rebellion had been suppressed. It was followed by trials in which harsh sentences were passed. During the summer and fall of 1918 some 20,000 former revolutionaries either were executed or died in prison camps, bringing the total losses of the war to more than 30,000 lives. A few of the revolutionary leaders, however, managed to escape to Soviet Russia, where a small contingent founded the Finnish Communist Party in Moscow; others continued their flight to the United States and western Europe, some gradually returning to Finland.

Political change. When the Civil War ended, it was

The new constitution

decided, during the summer of 1918, to make Finland a monarchy, and in October the German prince Frederick Charles of Hessen was chosen as king. With Germany's defeat in the war, however, General Mannerheim was designated regent, with the task of submitting a proposal for a new constitution. As it was obvious that Finland was to be a republic, the struggle now concerned presidential power. The liberal parties and the reorganized Social Democratic Party wanted power to be invested in Parliament, while the Conservatives wanted the president to have powers independent of Parliament. The strong position held by the Conservatives after the Civil War enabled them to force through their motion that the president should be chosen by popularly elected representatives, independent of Parliament, and also that he should possess a great deal more authority, especially regarding foreign policy, than at that time was usual for a head of state. After the new constitution had been confirmed on July 17, 1919, the Social Democrats positioned themselves behind the liberal National Progressive Party leader, Kaarlo Juho Ståhlberg, to make him the first president of Finland and to defeat the Conservative candidate Mannerheim, who had not convinced them of his loyalty to republicanism.

Agrarian reform. During the interwar years Finland, to a much greater extent than the rest of the Nordic countries, was an agrarian country. In 1918, 70 percent of the population was employed in agriculture and forestry, and by 1940 the figure was still as high as 57 percent. Paper and wooden articles were Finland's most important export commodities. By the Smallholdings Law of 1918 and by land reform in 1922, which allowed the expropriation of estates of more than 495 acres (200 hectares), an attempt was made to give tenant farmers and landless labourers their own smallholdings. More than 90,000 smallholdings were created, and since then the independent smallholders, who form the majority of the Agrarian Party (now the Centre Party), have been a major factor in Finnish politics.

Political parties. During Ståhlberg's presidency (1919–25), the right-wing parties and the Agrarian Party held power by means of coalitions. The president tried determinedly to minimize the recriminations of the Civil War, and in the course of time he granted amnesty to those who had received long terms of imprisonment. At the same time, the Social Democratic Party was reorganized under the leadership of Väinö Tanner with an exclusively reformist program. When Tanner in 1926 formed a Social Democratic minority government, which granted a general amnesty, the old differences from the Civil War had been almost eliminated. Lauri Kristian Relander, the Agrarian Party's candidate, was elected president in 1925.

Through the first decade of Finnish independence the Social Democratic Party remained the largest party in the Parliament. In the early 1920s the leftist wing of the Social Democrats separated from the party to preach Communism and succeeded in winning 27 seats at the 1922 election. It later changed its name from Socialist Labour Party to Labour Party, but this did not stop the police from arresting all of its parliamentary representatives for treason on the grounds of the party's revolutionary intent. The Communists, however, once more reorganized and worked closely with the Finnish Communist Party in the Soviet Union. In the following elections they were able to win about 20 seats in Parliament.

The Lapua Movement

As a reaction to the growing Finnish Communist Party, the Lapua (Lappo) Movement emerged and in the years 1929–32 attempted to force its demands through actions against Communist newspapers, acts of terrorism against individual citizens, and mass demonstrations. These actions, which were supported by the Conservatives and many members of the Agrarian Party, were at first successful. The Communists were prevented from taking part in the 1930 election, and the 66 Social Democrats were one too few in the Parliament to prevent the passage of an anti-Communist law. This law banned the public activities of the Communist Party, forced its members underground, and stripped them of their right to vote, virtually eliminating their influence on Finnish politics. In 1931 Svinhufvud was elected president with the help of the Lapua Movement. When the Lapua Movement shortly afterward turned its activities against the Social Democrats, too, and tried to seize power by force in the Mäntsälä coup attempt in 1932, the president intervened and managed in a radio speech to calm the rebellion. Another failure at this time was the law on the total prohibition of alcohol, introduced in 1919. As in the United States, the law resulted in a sharp increase in organized crime and smuggling, and after a referendum in 1932 it was repealed.

The language question. The 1919 constitution provided that both Finnish and Swedish should be the national languages. A younger radical generation now raised the demand for the supremacy of Finnish. The language controversy, which during the interwar period was a very bitterly fought issue, caused the position of the Swedish language to be progressively weakened toward the end of the 1930s. During World War II the laws governing language were revised, first in 1947 and again in 1961. They now guarantee equal status for Swedish, which remains an official language of the country and a required subject in Finnish schools.

Foreign policy. After the recognition of Finland as a sovereign state, two problems had to be faced. The first was in connection with the eastern boundary, where influential groups wished to annex East Karelia. By the Treaty of Tartu (Dorpat) in 1920, however, the boundary was unchanged except in the north, where Finland acquired a route to the Arctic Ocean and the harbour of Petsamo. The other problem concerned the Åland Islands (Finnish: Ahvenanmaa), which Sweden had temporarily occupied during the Finnish Civil War. The demands of the population of the islands to be united with Sweden were firmly rejected. The League of Nations settled the question in 1921 in accordance with Finland's wishes.

Finland's main security problems resulted from the threat from the Soviet Union. An attempt to solve this by a defense alliance with Estonia, Latvia, and Poland in 1922 failed when Parliament refused to ratify the agreement, and in 1932 a Finnish–Soviet nonaggression pact was signed. Despite this, relations between the two countries did not really improve, and they remained "neighbours against their will." During the second half of the 1930s a Finnish–Swedish defense association was planned that, among other things, would have brought about the rearming of Åland, but the Soviet Union objected to these plans and they could not be realized.

FINLAND DURING WORLD WAR II

The Treaty of Moscow

The Winter War. After Poland's defeat in the autumn of 1939, the Soviet Union, wishing to safeguard Leningrad, demanded from Finland a minor part of the Karelian Isthmus, a naval base at Hanko (Hangö), and some islands in the Gulf of Finland. When Finland rejected the demand, the Soviet Union launched an attack on Nov. 30, 1939. Immediately after the attack a coalition government was formed under Risto Ryti. Despite courageous resistance and a number of successful defense actions, the defense of the Karelian Isthmus broke down, and Finland had to initiate peace negotiations. By the Treaty of Moscow of March 12, 1940, Finland surrendered a large area of southeastern Finland, including the city of Viipuri (renamed Vyborg), and leased the peninsula of Hanko to the Soviet Union for 30 years.

Cooperation with Germany. After the Treaty of Moscow the plan for a Nordic defense union was resumed. The Soviet Union still objected, however, and the plan was thus abandoned. In December 1940 President Kyösti Kallio resigned, and Risto Ryti was elected in his place. When the tension between Germany and the Soviet Union grew in spring 1941, Finland approached Germany but did not conclude a formal agreement. Nevertheless, Finland, like Sweden after Norway's capitulation, allowed the transit of German troops. When Germany attacked the Soviet Union on June 22, 1941, therefore, German troops were already on Finnish territory, and Finland was ready for war; its submarines, in fact, were operating in Soviet waters. The "War of Continuation" (1941–44) began with a successful Finnish offensive that led to the capture of large areas of East Karelia. Some Finns were reluctant, however, to cross the old border of 1939, and the spirit of the Winter War that had united the Finns began to weaken. From the winter of 1942–43, Germany's defeats gave rise to a growing demand for peace in Finland. After the breakthrough of the Red Army on the Karelian Isthmus in June 1944, President Ryti resigned on August 1. He was succeeded by Marshal Gustaf Mannerheim, who began negotiations for an armistice. This was signed on Sept. 19, 1944, on condition that Finland recognize the Treaty of Moscow of 1940 and that all foreign (German) forces be evacuated. A pledge was given, moreover, to cede Petsamo; to lease an area near Porkkala, southwest of Helsinki, for a period of 50 years (in place of Hanko); and within 6 years to pay the equivalent of $300 million in goods for war reparations. In the meantime, however, the German army refused to leave the country, and, in a series of clashes that followed, it devastated great areas of northern Finland in its retreat. The final peace treaty, signed in Paris on Feb. 10, 1947, reiterated the conditions of the armistice agreement. (Jö.We./M.I.He.)

THE POSTWAR PERIOD

After the armistice in 1944 a coalition government was formed under the leadership of Juho Kusti Paasikivi. When conditions had been stabilized, Mannerheim resigned, and Paasikivi was elected president in his place in 1946. In 1956 the leader of the Agrarian Party, Urho Kekkonen, who acted as prime minister a number of times during the period 1950 to 1956, was elected president. He was reelected three times to the office, with an extension of his third term by the Parliament. When he resigned in 1981, he was succeeded by the Social Democrat Mauno Koivisto, who was reelected in 1988.

Paasikivi's tenure

Foreign policy. Under the leadership of Paasikivi and Kekkonen, relations with the Soviet Union were stabilized by a consistently friendly policy on the part of Finland. A concrete expression of the new foreign policy was the Agreement of Friendship, Cooperation, and Mutual Assistance concluded between Finland and the Soviet Union in 1948 and extended in 1955, 1970, and 1983. The agreement included a mutual defense provision and prohibited Finland from joining any organization considered hostile to the U.S.S.R. After war reparations had been paid in full, trade with the Soviet Union continued, rising to more than 25 percent of Finland's total during the 1980s. Further signs of the détente showed when the Soviet Union returned its base at Porkkala in 1955.

Relations with the Soviet Union, however, were not entirely without complications. After the elections of 1958, a coalition government under the leadership of the Social Democrat Karl August Fagerholm included certain members considered anti-Soviet. The Soviet Union responded by recalling its ambassador and canceling credits and orders in Finland. When the Finnish government was reconstructed, relations were again stabilized. During the autumn of 1961, when international relations were severely strained because of the Berlin crisis, the Soviet Union requested consultations in accordance with the 1948 agreement. President Kekkonen succeeded in inducing the Soviet Union to abandon its request. In 1985 the Soviets warned that a split in the Finnish Communist Party between the nationalist-reformist majority and the pro-Moscow minority would jeopardize Soviet-Finnish relations, but the split occurred in 1986 without straining relations.

Nordic cooperation. Finland became a member of the United Nations and of the Nordic Council in 1955. Nordic cooperation has led to many shared policies in Finland, Denmark, Iceland, Norway, and Sweden. These include free movement across the borders of these five countries, the gradual development of a common and free labour market, and various political, economic, and cultural measures. In 1986 Finland became a full member of the European Free Trade Association (EFTA).

Domestic affairs. During the early postwar years, Finland confronted economic difficulties. After World War II the country had to absorb about 300,000 refugees from the areas ceded to the Soviet Union and at the same time pay war reparations. Despite these obstacles Finland quickly recovered. The war reparations brought about rapid expansion in the metal and shipbuilding industries, and the timber trade soon resumed exporting and quickly exceeded its prewar level. The rebuilding and colonization required to resettle the refugees, however, were such a strain on the country's economy that inflation ensued; as a result Finland devalued its currency repeatedly.

After the armistice, the new Finnish Communist Party held a strong position. When in the spring of 1948 it was alleged that the party had planned a coup, Parliament forced the Communist minister of the interior to resign. Parliamentary elections in the autumn of 1948 resulted in a Social Democratic government under the leadership of Fagerholm. Governments changed rapidly and consisted of various party coalitions during the 1950s, in most cases under the leadership of the Agrarian Party or the Social Democrats. During this period, however, both the Conservative National Coalition Party and the leftist Finnish People's Democratic League, which included the Finnish Communist Party, were excluded from the government.

Forming and keeping a government in Finland was very difficult because of the proliferation of political parties; no one party, and often no party group, could command a majority in Parliament. As a consequence, there were many nonpolitical cabinets composed of civil servants appointed by the president. With continuing economic growth and because of internal disputes, Communist Party influence diminished after the 1970s, and after the party's split in the mid-1980s the Communists suffered severe losses in the 1987 election. The Conservatives gained and formed a coalition government under Conservative Prime Minister Harri Holkeri.

RECENT DEVELOPMENTS

In 1991 a new cabinet, formed by major nonsocialist parties and with the Centre's Esko Aho as prime minister, immediately faced Finland's worst economic recession since the 1940s. During the early 1990s production dropped sharply and unemployment skyrocketed, largely because trade with Russia plummeted from the levels of the Soviet era. Following the Soviet Union's demise in 1991, Finland moved to end the old mutual defense agreement. A new accord was reached with Russia in 1992, in which the two countries simply pledged to settle disputes between them peacefully. Finland, now freed from any restrictions, applied for membership in the European Community, which formed the European Union (EU) in 1993. When Finland joined the EU in 1995, it left EFTA. Economic recovery came slowly during the mid-1990s, as export markets gradually shifted toward the EU countries. The government tried to cut expenditures, notably on social programs. The public expressed its displeasure with the slow pace of recovery by ousting the Centre from the government in the elections of 1995.

Social Democrat Paavo Lipponen formed a cabinet from a broad-based coalition that included, for the first time, members of the environmentalist Green Union. Lipponen's government moved cautiously toward closer military union with western Europe and a more assertive stance toward Russia. Finland joined other EU countries in adopting the common European currency, the euro, in 1999, even as other Scandinavian countries resisted incorporation into the euro zone. Meanwhile, led by a strong high-technology sector, Finland's economy prospered at the turn of the 21st century. When President Martti Ahtisaari (who had succeeded Koivisto in 1994) left office in 2000, Social Democrat Tarja Halonen became Finland's first woman president. When Russian president Vladimir Putin refused to discuss the return of Karelia, Halonen responded firmly that the matter was not closed. Free at last from fear of Soviet domination, an economically robust Finland enjoyed full independence of action for perhaps the first time in its history. (Jö.We./M.I.He./Ed.)

Physical and human geography. W.R. MEAD, *An Historical Geography of Scandinavia* (1981); and KALEVI RIKKINEN, *A Geography of Finland,* trans. from Finnish (1992), provide comprehensive surveys. A broad interpretive treatment, with a look at the social customs of Finland, is found in PHILIP WARD, *Finnish Cities: Travels in Helsinki, Turku, Tampere, and Lapland* (1987).

Ethnological studies include AURÉLIEN SAUVAGEOT, *Les Anciens Finnois* (1961); and WILLIAM A. WILSON, *Folklore and Nationalism in Modern Finland* (1976). Social life and customs are explored in AINI RAJANEN, *Of Finnish Ways* (1981); CAJ BREMER and ANTERO RAEVUORI, *The World of the Sauna* (1986; originally published in Finnish, 1985); ANTTI TUURI, *The Face of Finland,* ed. by PAULI KOJO, trans. from Finnish (1983); and ANNEKE LIPSANEN, *The Finnish Folk Year: A Perpetual Diary & Book of Days, Ways, and Customs* (1987).

Finland's economy is discussed in FRED SINGLETON, *The Economy of Finland in the Twentieth Century* (1986); RIITTA HJERPPE, *The Finnish Economy, 1860–1985: Growth and Structural Change* (1989; originally published in Finnish, 1988); ORGANISATION FOR ECONOMIC CO-OPERATION AND DEVELOPMENT, *Reviews of National Science and Technology Policy: Finland* (1987); *Environmental High-Technology from Finland* (1986), published by the Ministry of the Environment; *Economic Survey* (annual), published by the Ministry of Finance; and *Finnish Industry,* rev. ed. (1982), an overview of developments, published by the Bank of Finland.

Government and politics are analyzed in D.G. KIRBY, *Finland in the Twentieth Century* (1979); ANTHONY F. UPTON, PETER P. ROHOE, and A. SPARRING, *Communism in Scandinavia and Finland* (also published as *The Communist Parties of Scandinavia and Finland,* 1973); JUHANI MYLLY and R. MICHAEL BERRY (eds.), *Political Parties in Finland* (1984); JAAKKO NOUSIAINEN, *The Finnish Political System* (1971; originally published in Finnish, 3rd ed., 1967); DAVID ARTER, *Politics and Policy-Making in Finland* (1987); and RISTO ALAPURO, *State and Revolution in Finland* (1988).

Finnish architecture and design are discussed in J.M. RICHARDS, *800 Years of Finnish Architecture* (1978); ERIK KRUSKOPF, *Finnish Design, 1875–1975: 100 Years of Finnish Industrial Design* (1975); ELIZABETH GAYNOR, *Finland, Living Design* (1984, reissued 1995); and JAAKKO LINTINEN *et al., Finnish Vision: Modern Art, Architecture, and Design,* trans. from Finnish (1983). Other studies of national art and culture include JOHN BOULTON SMITH, *The Golden Age of Finnish Art: Art Nouveau and the National Spirit,* 2nd rev. ed. (1985); MARIANNE AAV and KAJ KALIN, *Form Finland,* trans. from Finnish (1986), on decorative arts; JAAKKO AHOKAS, *A History of Finnish Literature* (1973); MATTI KUUSI, KEITH BOSLEY, and MICHAEL BRANCH (eds. and trans.), *Finnish Folk Poetry: Epic: An Anthology in Finnish and English* (1977); KAI LAITINEN, *Literature of Finland: An Outline*, 2nd ed., trans. from Finnish (1994); *Kalevala,* ed. by AIVI GALLEN-KALLELA and trans. by W.F. KIRBY (1986), a jubilee edition of the national epic, illustrated by AKSELI GALLEN-KALLELA; *The Kalevala: Epic of the Finnish People*, trans. by EINO FRIBERG and ed. by GEORGE C. SCHOOLFIELD (1988); ANTONY HODGSON, *Scandinavian Music: Finland & Sweden* (1984); PAAVO HELISTÖ, *Music in Finland* (1980); and MAIJA SAVUTIE, *Finnish Theatre: A Northern Part of World Theatre,* trans. from Finnish (1980).

History. General works on Finnish history include JOHN H. WUORINEN, *A History of Finland* (1965); EINO JUTIKKALA and KAUKO PIRINEN, *A History of Finland,* 4th rev. ed. (1984; originally published in Finnish, 1966); EINO JUTIKKALA, *Atlas of Finnish History,* 2nd rev. ed. (1959); BYRON J. NORDSTROM (ed.), *Dictionary of Scandinavian History* (1986); FRED SINGLETON, *A Short History of Finland* (1989); and MATTI KLINGE, *A Brief History of Finland,* trans. from Finnish, 10th ed. (1994).

More detailed discussions of events in the 19th and 20th centuries are available in JUHANI PAASIVIRTA, *Finland and Europe: International Crises in the Period of Autonomy, 1808–1914,* ed. and abridged by D.G. KIRBY (1981; originally published in Finnish, 1978); L.A. PUNTILA, *The Political History of Finland, 1809–1966* (1974; originally published in Finnish, 5th rev. and improved ed., 1971); ANTHONY F. UPTON, *The Finnish Revolution, 1917–1918* (1980), a comprehensive analysis, and *Finland, 1939–1940* (1974); and MAX JAKOBSON, *Finland Survived: An Account of the Finnish-Soviet Winter War, 1939–1940,* 2nd enlarged ed. (1984).

Foreign relations are the main topic of TUOMO POLVINEN, *Between East and West: Finland in International Politics, 1944–1947,* ed. and trans. by D.G. KIRBY and PETER HERRING (1986; originally published in Finnish, 3 vol., 1979–81); ROY ALLISON, *Finland's Relations with the Soviet Union, 1944–1984* (1985); R. MICHAEL BERRY, *American Foreign Policy and the Finnish Exception* (1987); and MAX JAKOBSON, *Finland: Myth and Reality* (1987). The *Yearbook of Finnish Foreign Policy,* published by the Finnish Institute of International Affairs, is another helpful source. (I.Su./M.I.He./Ed.)

Fishes

The term fish is applied to a variety of cold-blooded aquatic vertebrates of several evolutionary lines. It describes a life-form rather than a taxonomic group. As members of the phylum Chordata, fish share certain features with other vertebrates. These features are gill slits at some point in the life cycle, a notochord, or skeletal supporting rod, a dorsal hollow nerve cord, and a tail. Living fishes represent about five classes, which are as distinct from one another as are the four classes of familiar air-breathing animals—amphibians, reptiles, birds, and mammals. For example, the jawless fishes (agnathans) are the only fishes that have a suctorial, or filter-feeding, mouth, a feature which makes them dependent on an essentially parasitic way of life. They have either no fins or poorly developed ones. Extant examples of the agnathans are the lampreys and the hagfishes. As the name implies, the skeletons of fishes of the class Chondrichthyes (*chondr,* "cartilage," and *ichthyes,* "fish") are made entirely of cartilage. Modern fish of this class lack a swim bladder, and their scales and teeth are made up of the same placoid material. Sharks, skates, and rays are examples of cartilaginous fishes. The bony fishes are by far the largest class. Examples range from the tiny sea horse to the 450-kilogram (1,000-pound) blue marlin, from the flat soles and flounders to the boxy puffers and sunfishes. Unlike those of the cartilaginous fishes, the scales of bony fishes, when present, grow throughout life and are made up of thin, overlapping plates of bone. Bony fishes also have an operculum that covers the gill slits.

The study of fishes, the science of ichthyology, is of broad importance. There are many reasons why fishes are of interest to humans; the most important is their relationship with and dependence on the environment. A more obvious reason for interest in fishes is their role as a moderate but important part of the world's food supply. This resource, once thought unlimited, is now realized to be finite and in delicate balance with the biological, chemical, and physical factors of the aquatic environment. Overfishing, pollution, and alteration of the environment are the chief enemies of proper fisheries management, both in fresh waters and in the ocean. (For a detailed discussion of the technology and economics of fisheries, see FISHING, COMMERCIAL.)

Another practical reason for studying fishes is their use in disease control. As predators on mosquito larvae, they help curb malaria and other mosquito-borne diseases. Fishes are valuable laboratory animals in many aspects of medical and biological research. For example, the readiness of many fishes to acclimate to captivity has allowed biologists to study behaviour, physiology, and even ecology under relatively natural conditions. Fishes have been especially important in the study of animal behaviour where research on fishes has provided a broad base for the understanding of the more flexible behaviour of the higher vertebrates.

There are aesthetic and recreational reasons for an interest in fishes. Millions of people keep live fishes in home aquariums for the simple pleasure of observing the beauty and behaviour of animals otherwise unfamiliar to them. To many, aquarium fishes provide a personal challenge, allowing them to test their ability to keep a small section of the natural environment in their homes. Sportfishing is another way of enjoying the natural environment, also indulged in by millions of people every year. Interest in aquarium fishes and sportfishing support multimillion-dollar industries throughout the world.

As mentioned above, the fishes represent several classes of vertebrates rather than a single taxonomic group. This article presents a comparative study of all fish groups, including those that are now extinct, with emphasis on their structural diversity, natural history, and evolutionary relationships. The major classes of living fishes—arranged in accordance with the complete *Annotated classification* (see outline)—are treated individually. Special attention is devoted to the teleosts (infraclass Teleostei), or bony fishes, a group that includes most of the world's important sport and commercial fishes. (S.H.W./Ed.)

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 312, and the *Index.*

The article is divided into the following sections:

FISHES: A COMPARATIVE STUDY

GENERAL FEATURES

Structural diversity. Fishes have been in existence for more than 450,000,000 years, during which time they have evolved repeatedly to fit into almost every conceivable type of aquatic habitat. In a sense, land vertebrates are simply highly modified fishes, for when fishes colonized the land habitat they became tetrapod (four-legged) land vertebrates. The popular conception of a fish as a slippery, streamlined aquatic animal that possesses fins and breathes by gills applies to many fishes, but far more fishes deviate from that conception than conform to it. For example, the body is elongate in many forms and greatly shortened in others; the body is flattened in some (principally in bottom-dwelling fishes) and laterally compressed in many others; the fins may be elaborately extended, forming intricate shapes, or they may be reduced or even lost; and the positions of the mouth, eyes, nostrils, and gill openings vary widely. Air breathers have appeared in several evolutionary lines.

Many fishes are cryptically coloured and shaped, closely matching their respective environments; others are among the most brilliantly coloured of all organisms, with a wide range of hues, often of striking intensity, on a single individual. The brilliance of pigments may be enhanced by the surface structure of the fish, so that it almost seems to glow. A number of unrelated fishes have actual light-producing organs. Many fishes are able to alter their coloration, some for the purpose of camouflage, others for the enhancement of behavioral signals.

Fishes range in adult length from less than 10 millimetres (2/5 inches) to more than 20 metres (60 feet) and in weight from about 1.5 grams (less than 1/16 ounce) to many thousands of kilograms. Some live in shallow thermal springs at temperatures slightly above 42° C (100° F), others in cold Arctic seas a few degrees below 0° C (32° F) or in cold deep waters more than 10,000 metres (3,500 feet) beneath the ocean surface. The structural and, especially, the physiological adaptations for life at such extremes are relatively poorly known and provide the scientifically curious with great incentive for study.

Distribution and abundance. Almost all natural bodies of water bear fish life, the exceptions being very hot thermal ponds and extremely salt-alkaline lakes such as the Dead Sea and Great Salt Lake in Utah. The present distribution of fishes is a result of the geological history and development of the Earth as well as the ability of fishes to undergo evolutionary change and to adapt to the available habitats. Fishes may be seen to be distributed according to habitat and according to geographical area. Major habitat differences are marine and fresh waters. For the most part the fishes in them, even in adjacent areas, are different, but some, such as the salmon, migrate from one to the other. The freshwater habitat may be seen to be of many kinds. Fishes found in mountain torrents, Arctic lakes, tropical lakes, temperate streams, and tropical rivers will all differ from each other both in obvious gross structure and in physiological attributes. Even in closely adjacent habitats where, for example, a tropical mountain torrent enters a lowland stream, the fish fauna will differ. Marine habitats can be divided into deep ocean floors (benthic), midwater oceanic (bathypelagic), surface oceanic (pelagic), rocky coast, sandy coast, muddy shores, bays, estuaries, and others. Also, for example, rocky coastal shores in tropical and temperate regions will have a different fish fauna, even when such habitats occur along the same coastline.

Habitats

Although much is known about the present geographical distribution of fishes, far less is known about how that distribution came about. Many parts of the fish fauna of the fresh waters of North America and Eurasia are related and undoubtedly have a common origin. The faunas of Africa and South America are related, extremely old, and probably an expression of the drifting apart of the two continents. The fauna of southern Asia is related to that of central Asia and some of it appears to have entered Africa. The extremely large shore fish faunas of the Indian and tropical Pacific oceans comprise a related complex, but the tropical shore fauna of the Atlantic, although containing Indo-Pacific components, is relatively limited and probably younger. The Arctic and Antarctic marine faunas are quite different from each other. The shore fauna of the North Pacific is quite distinct, and that of the North Atlantic more limited and probably younger. Pelagic oceanic fishes, especially those in deep waters, are similar the world over, showing little geographical isolation in terms of family groups. The deep oceanic habitat is very much the same throughout the world, but species differences do exist, showing geographical areas determined by oceanic currents.

NATURAL HISTORY

Life history. All aspects of the life of a fish are closely correlated with adaptation to the total environment, physical, chemical, and biological. In studies of fish life, all the interdependent aspects of their life, such as behaviour, locomotion, reproduction, and physical and physiological characteristics, must be taken into account.

Correlated with their adaptation to an extremely wide variety of habitats is the extremely wide variety of life cycles that fishes display. The great majority hatch from relatively small eggs a few days to several weeks or more after the eggs are scattered in the water. Newly hatched young are still partially undeveloped and are called larvae until body structures such as fins, skeleton, and some organs are fully formed. Larval life is often very short, usually less than a few weeks, but it can be very long, some lampreys continuing as larvae for at least five years. Young and larval fishes, before reaching sexual maturity, must grow considerably, and their small size and other factors often dictate that they live in a habitat different than that of the adults. For example, some tropical marine shore fishes have pelagic larvae. Larval food also is different and they often live in shallow waters, where they may be less exposed to predators.

Longevity

After the fish reaches adult size, the length of its life is subject to many factors, such as innate rates of aging, predation pressure, and the nature of the local climate. The longevity of a species in the protected environment of an aquarium may have nothing to do with how long members of that species live in the wild. Many small fishes live only one to three years at the most. In a few large species some individuals may live as long as 10 or 20 years or even longer.

Behaviour. Fish behaviour is a complicated and varied subject. As in almost all animals with a central nervous system, the nature of a response of an individual fish to stimuli from its environment depends upon the inherited characteristics of its nervous system, on what it has learned from past experience, and on the nature of the stimuli. Compared with the variety of human responses, however, that of a fish is stereotyped, not subject to much modification by "thought" or learning, and investigators must guard against anthropomorphic interpretations of fish behaviour.

Fishes perceive the world around them by the usual senses of sight, smell, hearing, touch, and taste and by special lateral-line water-current detectors. In the few fishes that generate electric fields, a process that might best be called electrolocation aids in perception. One or another of these senses often is emphasized at the expense of others depending upon the fish's other adaptations. In fishes with large eyes the sense of smell may be reduced; others, with small eyes, hunt and feed primarily by smell (*e.g.,* some eels).

Specialized behaviour is primarily concerned with the three most important activities in the fish's life: feeding, reproduction, and escape from enemies. Schooling behaviour of sardines on the high seas, for instance, is largely a protective device to avoid enemies, but it is also associated with and modified by their breeding and feeding requirements. Predatory fishes are most often solitary, lying in wait to dart suddenly after their prey, a kind of locomotion impossible for beaked parrot fishes, which feed on coral, swimming in small groups from one coral head to the next.

Sleep

Sleep in fishes, all of which lack true eyelids, consists of a seemingly listless state in which the fish maintains its balance but moves slowly. If attacked or disturbed, most can dart away. A few kinds of fishes lie on the bottom to sleep. Most catfishes, some loaches, and some eels and electric fishes are strictly nocturnal, being active and hunting for food during the night and retiring during the day to holes, thick vegetation, or other protective parts of the environment.

Communication between members of a species or between members of two or more species often is extremely important, especially in breeding behaviour (see below *Reproduction*). The mode of communication may be visual, as between the small so-called cleaner fish and a large fish of a very different species. The larger fish often allows the cleaner to enter its mouth to remove gill parasites. The cleaner is recognized by its distinctive colour and actions and therefore is not eaten, even if the larger fish is normally a predator.

Locomotion. Many fishes have a streamlined body and swim freely in the open water. Fish locomotion is closely correlated with habitat and ecological niche (the general position of the animal to its environment).

Many fishes in both marine and fresh waters swim at the surface and have mouths adapted to feed best (and sometimes only) at the surface. Often such fishes are long and slender, able to dart at surface insects or at other surface fishes and in turn to dart away from predators; needlefishes, halfbeaks, and topminnows are good examples. Oceanic flying fishes escape their predators by gathering speed above the water surface, with the lower lobe of the tail providing thrust in the water. They then glide hundreds of yards on enlarged, winglike pectoral and pelvic fins. South American freshwater flying fishes escape their enemies by jumping and propelling their strongly keeled bodies out of the water with their pectoral fins, which function as flapping wings.

So-called midwater swimmers, the most common type of fish, are of many kinds and live in many habitats. The powerful fusiform tunas and the trouts, for example, are adapted for strong, fast swimming, the first to capture prey speedily in the open ocean, the second to cope with the swift currents of streams and rivers. The trout body form is well adapted to many habitats. Fishes that live in relatively quiet waters such as bays or lake shores or slow rivers usually are not strong, fast swimmers but are capable of short, quick bursts of speed to escape a predator. Many of these fishes have their sides flattened, examples being the sunfish and the freshwater angelfish of aquarists. Fish associated with the bottom or substrate usually are slow swimmers. Open-water plankton-feeding fishes almost always remain fusiform and capable of rapid, strong movement (for example, sardines and herrings of the open ocean and also many small minnows of streams and lakes).

Special adaptations of bottom dwellers

Bottom-living fishes are of many kinds and have undergone many types of modification of their body shape and swimming habits. Rays, which evolved from strong swimming, midwater sharks, usually stay close to the bottom and move by undulating their large pectoral fins. Flounders live in a similar habitat and move over the bottom by undulating the entire body. Many bottom fishes dart from place to place, resting on the bottom between movements, a motion common in gobies. One goby relative, the mudskipper, has taken to living at the edge of pools along the shore of muddy mangrove swamps. It escapes its enemies by flipping rapidly over the mud, out of the water. Some catfishes, synbranchid eels, the so-called climbing perch, and a few other fishes venture out over damp ground to find more promising waters than those that they left. They move by wriggling their bodies, sometimes using strong pectoral fins; most have accessory air-breathing organs. Many bottom-dwelling fishes live in mud holes or rocky crevices. Marine eels and gobies commonly are found in such habitats and for the most part venture far beyond their cavelike homes. Some bottom dwellers, such as the clingfishes (Gobiesocidae), have developed powerful adhesive disks that enable them to remain in place on the substrate in areas such as rocky coasts where the action of the waves is great.

Reproduction. The methods of reproduction in fishes are varied, but most fishes lay a large number of small eggs, fertilized and scattered outside of the body. The eggs of pelagic fishes usually remain suspended in the open water. Many shore and freshwater fishes lay eggs on the bottom or among plants. Some have adhesive eggs. The mortality of the young and especially of the eggs is very high, and often only a few individuals grow to maturity out of hundreds, thousands, and in some cases millions of eggs laid.

Males produce sperm, usually as a milky white substance called milt, in two (sometimes one) testes within the body cavity. In bony fishes a sperm duct leads from each testis to a urogenital opening behind the vent or anus. In sharks and rays and in cyclostomes the duct leads to a cloaca. Sometimes the pelvic fins are modified to help transmit the milt to the eggs at the female's vent or on the substrate where the female has placed them. Sometimes accessory organs are used to fertilize females internally—for example, the claspers of many sharks and rays.

In the females the eggs are formed in two ovaries (sometimes only one) and pass through the ovaries to the urogenital opening and to the outside. In some fishes the eggs are fertilized internally but shed before development takes place. Members of about a dozen families each of bony fishes (teleosts) and sharks bear live young. Many skates and rays also bear live young. In some bony fishes the eggs simply develop within the female, the young emerging when the eggs hatch (ovoviviparous). Others develop within the ovary and are nourished by ovarian tissues after hatching (viviparous). There are also other methods utilized by fishes to nourish young within the female. In all live-bearers the young are born at a relatively large size and are few in number. In one family of primarily marine fishes, the surfperches from the Pacific coast of North America, Japan, and Korea, the males of at least one species appear to be born sexually mature, although they are not fully grown.

Hermaphroditism

Some fishes are hermaphroditic, an individual producing both sperm and eggs, usually at different stages of its life. Self-fertilization, however, is probably rare.

Successful reproduction and in many cases defense of the eggs and young is assured by rather stereotyped but often elaborate courtship and parental behaviour, either by the male or the female or both. Some fishes prepare nests by hollowing out depressions in the sand bottom (cichlids, for example), build nests with plant materials and sticky threads excreted by the kidneys (sticklebacks), or blow a cluster of mucus-covered bubbles at the water surface (gouramis). The eggs are laid in these structures. Some varieties of cichlids and catfishes incubate eggs in their mouths.

Some fishes, such as salmon, undergo long migrations from the ocean and up large rivers to spawn in gravel beds where they themselves hatched (anadromous fishes). Others undertake shorter migrations from lakes into streams or in other ways enter for spawning habitats that they do not ordinarily occupy.

FORM AND FUNCTION

Body plan. The basic structure and function of the fish body is similar to those of all other vertebrates. The usual four types of tissues are present: surface or epithelial, connective (bone, cartilage, and fibrous tissues, as well as their derivative, blood), nerve, and muscle tissues. In addition, the organs and organ systems parallel those of other vertebrates.

The typical fish body is streamlined and spindle-shaped, with an anterior head, gill apparatus, and heart, the latter lying in the midline just below the gill chamber (see Figure 1). The body cavity, containing the vital organs, is situated behind the head in the lower anterior part of the body. The anus usually marks the posterior termination of the body cavity and most often occurs just in front of the

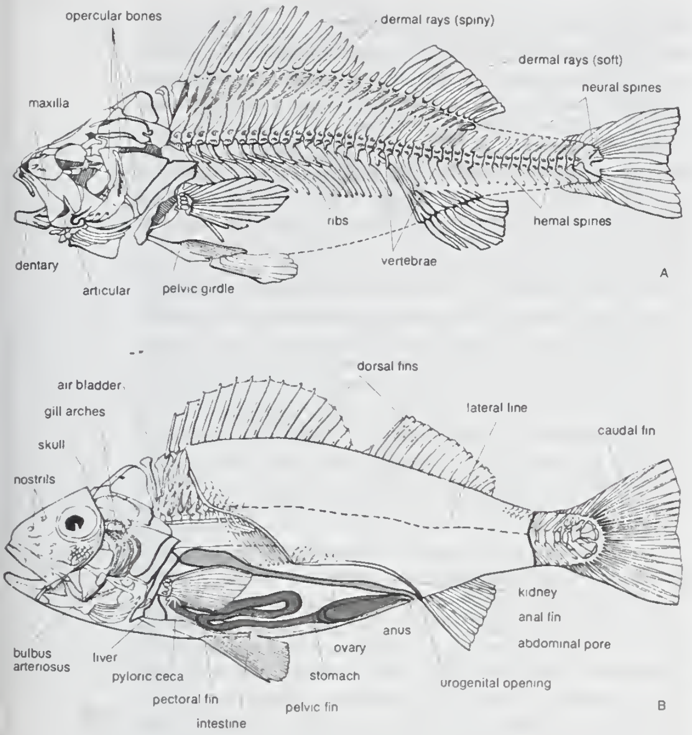

Figure 1: *Internal structure of fishes.*
(A) Skeleton of a perch. (B) Dissection of perch.

base of the anal fin. The spinal cord and vertebral column continue from the posterior part of the head to the base of the tail fin, passing dorsal to the body cavity and through the caudal (tail) region behind the body cavity. Most of the body is of muscular tissue, a high proportion of which is necessitated by swimming. In the course of evolution this basic body plan has been modified repeatedly into the many varieties of fish shapes that exist today.

Skeleton

The skeleton forms an integral part of the fish's locomotion system, as well as serving to protect vital parts. The internal skeleton consists of the skull bones (except for the roofing bones of the head, which are really part of the external skeleton), vertebral column, and the fin supports (fin rays). The fin supports are derived from the external skeleton but will be treated here because of their close functional relationship to the internal skeleton. The internal skeleton of cyclostomes, sharks, and rays is of cartilage; that of many fossil groups and some primitive living fishes is mostly of cartilage but may include some bone. In place of the vertebral column, the earliest vertebrates had a fully developed notochord, a flexible stiff rod of viscous cells surrounded by a strong fibrous sheath. During the evolution of modern fishes the rod was replaced in part by cartilage and then by ossified cartilage. Sharks and rays retain a cartilaginous vertebral column; bony fishes have spool-shaped vertebrae that in the more primitive living forms only partially replace the notochord. The skull, including the gill arches and jaws of bony fishes, is fully, or at least partially, ossified. That of sharks and rays remains cartilaginous, at times partially replaced by calcium deposits but never by true bone.

The supportive elements of the fins (basal or radial bones or both) have changed greatly during fish evolution. Some of these changes are described in the sections below (*Evolution and paleontology; Classification*). Most fishes possess a single dorsal fin on the midline of the back. Many have two and a few have three dorsal fins. The other fins are the single tail and anal fins and paired pelvic and pectoral fins. A small fin, the adipose fin, almost always without fin rays, occurs in many of the relatively primitive teleosts (such as trout) on the back near the base of the caudal fin.

The skin. The skin of a fish must serve many functions. It aids in maintaining the osmotic balance, provides physical protection for the body, is the site of coloration, contains sensory receptors, and, in some fishes, functions in respiration. Mucous glands, which aid in maintaining the water balance and offer protection from bacteria, are extremely numerous in fish skin, especially in cyclostomes and teleosts. Since mucous glands are present in the modern lampreys it is reasonable to assume that they were present in primitive fishes, such as the ancient Silurian and Devonian agnaths. Protection from abrasion and predation is another function of the fish skin, and dermal (skin) bone arose early in fish evolution in response to this need. It is thought that bone first evolved in skin and only later invaded the cartilaginous areas of the fish's body, to provide additional support and protection. There is some argument as to which came first, cartilage or bone, and fossil evidence does not settle the question. In any event, dermal bone has played an important part in fish evolution and has different characteristics in different groups of fishes. Several groups are characterized at least in part by the kind of bony scales they possess.

Types of scales

Scales have played an important part in the evolution of fishes. Primitive fishes usually had thick bony plates or thick scales in several layers of bone, enamel, and related substances. Modern teleost fishes have scales of bone, which, while still protective, allow much more freedom of motion in the body. A few modern teleosts (some catfishes, sticklebacks, and others) have secondarily acquired bony plates in the skin. Modern and early sharks possessed placoid scales, a relatively primitive type of scale with a toothlike structure, consisting of an outside layer of enamel-like substance (vitrodentine), an inner layer of dentine, and a pulp cavity containing nerves and blood vessels. Primitive bony fishes had thick scales of either the ganoid or the cosmoid type. Cosmoid scales have a hard, enamel-like outer layer, an inner layer of cosmine (a form of dentine), and then a layer of vascular bone (isopedine). In ganoid scales the hard outer layer is different chemically and is called ganoin. Under this is a cosmine-like layer and then a vascular bony layer. The thin, translucent bony scales of modern fishes, called cycloid and ctenoid scales (the latter distinguished by serrations at the edges), lack enameloid and dentine layers.

Skin has several other functions in fishes. It is well supplied with nerve endings and presumably receives tactile, thermal, and pain stimuli. Skin is well supplied with blood vessels. Some fishes breathe in part through the skin, by the exchange of oxygen and carbon dioxide between the surrounding water and numerous small blood vessels near the skin surface.

Coloration

Skin serves as protection through the control of coloration. Fishes exhibit an almost limitless range of colours. The colours often blend closely with the surroundings, effectively hiding the animal. Many fishes use bright colours for territorial advertisement or as recognition marks for other members of their own species, or sometimes for members of other species. Many fishes can change their colour to a greater or lesser degree, by expansion and con-

From T Storer and R Usinger *General Zoology* (1957) McGraw-Hill Book Company

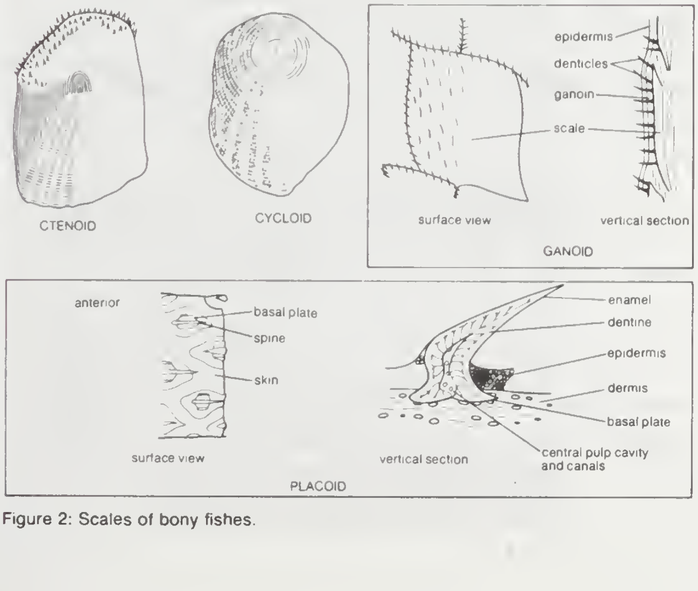

Figure 2: Scales of bony fishes.

traction of the pigment cells (chromatophores). Black pigment cells (melanophores), of almost universal occurrence in fishes, are often juxtaposed with other pigment cells. When placed near iridocytes or leucophores (bearing the silvery or white pigment guanine) melanophores produce structural colours of blue and green. These colours are often extremely intense, because they are formed by refraction of light through the needlelike crystals of guanine. The blue and green refracted colours are often relatively pure, lacking the red and yellow rays, which have been absorbed by the black pigment (melanin) of the melanophores. Yellow, orange, and red colours are produced by erythrophores, cells containing the appropriate carotenoid pigments. Other colours are produced by combinations of melanophores, erythrophores, and iridocytes.

The muscle system. The major portion of the body of most fishes consists of muscles. Most of the mass is trunk musculature, the fin muscles usually being relatively small. The caudal fin is usually the most powerful fin, with the largest amount of direct musculature. Its musculature is really a structural and functional continuation of the main musculature of the body. The body musculature is usually arranged in two rows of chevron-shaped segments on each side. Contractions of these segments, each attached to adjacent vertebrae and vertebral processes, bends the body on the vertebral joint, producing successive undulations of the body, passing from the head to the tail, and producing driving strokes of the tail. It is the latter that provides the strong forward movement for most fishes.

The digestive system. The digestive system, in a functional sense, starts at the mouth, with the teeth used to capture prey or collect plant foods. Mouth shape and tooth structure vary greatly in fishes, depending on the kind of food normally eaten. Most fishes are predacious, feeding on small invertebrates or other fishes and have simple conical teeth on the jaws, on at least some of the bones of the roof of the mouth, and on special gill arch structures just in front of the esophagus. The latter are throat teeth.

From B Dean, *Fishes Living and Fossil*, in A S Romer *The Vertebrate Body*, 4th ed (1970), W B Saunders Company

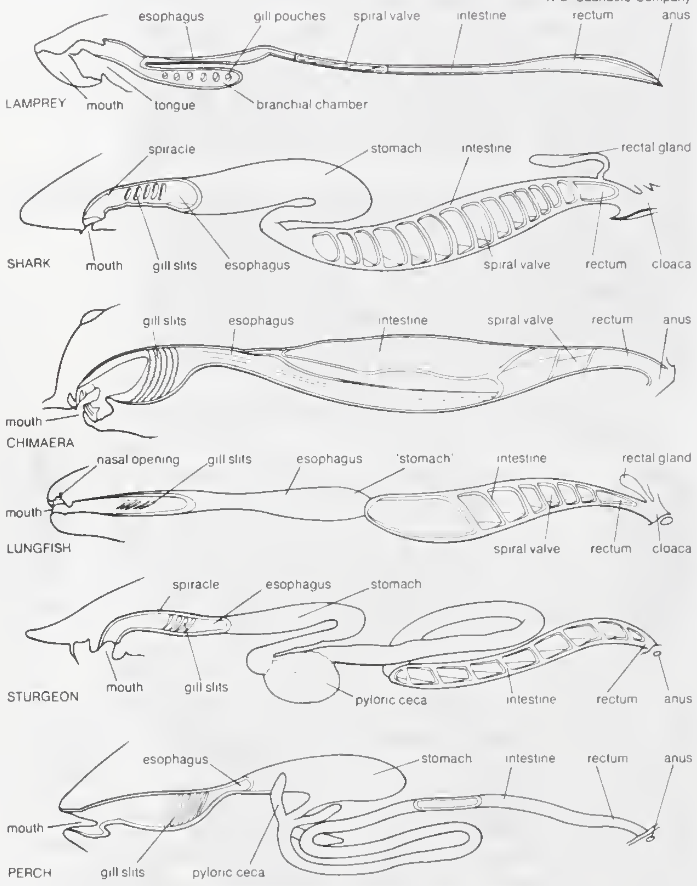

Figure 3: *Digestive tracts of various kinds of fishes.* Lampreys and chimaeras have no stomachs; the stomach of a lungfish is merely an enlargement of the esophagus.

Types of teeth

Most predacious fishes swallow their prey whole, and the teeth are used for grasping and holding prey, for orienting prey to be swallowed (head first) and for working the prey toward the esophagus. There are a variety of tooth types in fishes. Some, such as sharks and the piranhas, have cutting teeth for biting chunks out of their victims. A shark's tooth, although superficially like that of a piranha, appears in many respects to be a modified scale, while that of the piranha is like that of other bony fishes, consisting of dentine and enamel. Parrotfishes have beaklike mouths with short incisor-like teeth for breaking off coral and have heavy pavement-like throat teeth for crushing the coral. Some catfishes have small brushlike teeth, arranged in rows on the jaws, for scraping plant and animal growth from rocks. Many fishes (*e.g.*, the Cyprinidae or minnows) have no jaw teeth at all but have very strong throat teeth.

Some fishes gather planktonic food by straining it from their gill cavities with numerous elongate stiff rods (gill rakers), anchored by one end to the gill bars. The food collected on these rods is passed to the throat where it is swallowed. Most fishes have only short gill rakers that help keep food particles from escaping out the mouth cavity into the gill chamber.

Once reaching the throat, food enters a short, often greatly distensible esophagus, a simple tube with a muscular wall leading into a stomach. The stomach varies greatly in fishes, depending upon the diet. In most predacious fishes it is a simple straight or curved tube or pouch with a muscular wall and a glandular lining. Food is largely digested here and leaves the stomach in liquid form.

Between the stomach and the intestine, ducts enter the digestive tube from the liver and pancreas. The liver is a large, clearly defined organ. The pancreas may be imbedded in it, diffused through it, or broken into small parts spread along some of the intestine. The junction between the stomach and the intestine is marked by a muscular valve. Pyloric ceca (blind sacs) occur in some fishes at this junction and have a digestive or an absorptive function, or both.

The intestine itself is quite variable in length depending upon the diet. It is short in predacious forms, sometimes no longer than the body cavity, but long in herbivorous forms, being coiled and several times longer than the entire length of the fish in some species of South American catfishes. The intestine is primarily an organ for absorbing nutrients into the bloodstream. The larger its internal surface, the greater its absorptive efficiency, and a spiral valve is one method of increasing its absorption surface. Sharks, rays, chimaeras, lungfishes, surviving chondrosteans, holosteans, and even a few of the more primitive teleosts have a spiral valve or at least traces of it in the intestine. Most modern teleosts have increased the area of the intestinal walls by having numerous folds and villi (fingerlike projections) somewhat like those in man. Undigested substances are passed to the exterior through the anus in most teleost fishes. In lungfishes, sharks, and rays it is first passed through the cloaca, a common cavity receiving the intestinal opening and the ducts from the uro-genital system.

The respiratory system. Oxygen and carbon dioxide dissolve in water and most fishes exchange dissolved oxygen and carbon dioxide in water by means of the gills. The gills lie behind and to the side of the mouth cavity and consist of fleshy filaments supported by the gill arches and filled with blood vessels, which give gills a bright red colour. Water taken in continuously through the mouth passes backward between the gill bars and over the gill filaments, where the exchange of gases takes place. The gills are protected by a gill cover in teleosts and many other fishes, but by flaps of skin in sharks, rays, and some of the older fossil fish groups. The blood capillaries in the gill filaments are close to the gill surface to take up oxygen from the water and to give up excess carbon dioxide to the water.

Swim bladder

Most modern fishes have a hydrostatic (ballast) organ, called the swim bladder, that lies in the body cavity just below the kidney and above the stomach and intestine. It originated as a diverticulum of the digestive canal. In advanced teleosts, especially the acanthopterygians, the bladder has lost its connection with the digestive tract, a condition called physoclistic. The connection has been retained (physostomous) by many relatively primitive teleosts. In several unrelated lines of fishes the bladder has become specialized as a lung or, at least, as a highly vascularized accessory breathing organ. Some fishes with such accessory organs are obligate air breathers and will drown if denied access to the surface, even in well-oxygenated water. Fishes with a hydrostatic form of swim bladder can control their depth by regulating the amount of gas in the bladder. The gas, mostly oxygen, is secreted into the bladder by special glands, rendering the fish more buoyant; it is absorbed into the bloodstream by another special organ, reducing the overall buoyancy and allowing the fish to sink. Some deep-sea fishes may have oil in the bladder, rather than gas. Other deep-sea and some bottom-living forms have much reduced swim bladders or have lost the organ entirely.

The swim bladder of fishes follows the same developmental pattern as the lungs of land vertebrates. There is no doubt that the two structures have the same historical origin in primitive fishes. More or less intermediate forms still survive among the more primitive types of fishes such as the lungfishes *Lepidosiren* and *Protopterus*.

The circulatory system. The circulatory, or blood vascular, system consists of the heart, the arteries, the capillaries, and the veins: it is in the capillaries that the interchange of oxygen, carbon dioxide, nutrients, and other substances such as hormones and waste products takes place. The capillaries in turn lead to the veins, which return the venous blood with its waste products to the heart, kidneys, and gills. There are two kinds of capillary beds, those in the gills and those in the rest of the body. The heart, a folded continuous muscular tube with three or four sacklike enlargements, undergoes rhythmic contractions, and receives venous blood in a sinus venosus. It then passes the blood to an auricle and then into a thick, muscular pump, the ventricle. From the ventricle the blood goes to a bulbous structure at the base of a ventral aorta just below the gills. The blood then passes to the afferent (receiving) arteries of the gill arches and then to the gill capillaries. There waste gases are given off to the environment and oxygen is absorbed. From there the oxygenated blood enters efferent (exuant) arteries of the gill arches and then into the dorsal aorta. From there blood is distributed to the tissues and organs of the body. One-way valves prevent backflow. The circulation of fishes thus differs from that of the reptiles, birds, and mammals, in that oxygenated blood is not returned to the heart prior to distribution to the other parts of the body.

Excretory organs. The primary excretory organ in fishes, as in other vertebrates, is the kidney. In fishes some excretion also takes place in the digestive tract, skin, and especially the gills (where ammonia is given off). Compared with land vertebrates, fishes have a special problem in maintaining their internal environment at a constant concentration of water and dissolved substances, such as salts. Proper balance of the internal environment (homeostasis) of a fish is in a great part maintained by the excretory system, especially the kidney.

Water balance

The kidney, gills, and skin play an important role in maintaining a fish's internal environment and checking the effects of osmosis. Marine fishes live in an environment in which the water around them has a greater concentration of salts than they can have inside their body and still maintain life. Freshwater fishes, on the other hand, live in water with a much lower concentration of salts than they require inside their bodies. Osmosis tends to promote the loss of water from the body of a marine fish and absorption of water by that of a freshwater fish. Mucus in the skin tends to slow the process but is not a sufficient barrier to prevent the movement of fluids through the permeable skin. When solutions on two sides of a permeable membrane have different concentrations of dissolved substances, water will pass through the membrane into the more concentrated solution, while the dissolved chemicals move into the area of lower concentration (diffusion).

The kidney of freshwater fishes is often larger in relation to body weight than that of marine fishes. In both groups the kidney excretes wastes from the body, but that of freshwater fishes also excretes large amounts of water, counteracting the water absorbed through the skin. Freshwater fishes tend to lose salt to the environment and must replace it. They get some salt from their food, but the gills and skin inside the mouth actively absorb salt from water passed through the mouth. This absorption is performed by special cells capable (like those of the kidney) of moving salts against the diffusion gradient. Freshwater fishes drink very little water and take in little water in their food.

Marine fishes must conserve water, therefore their kidneys excrete little water. To maintain their water balance marine fishes drink large quantities of seawater, retaining most of the water and excreting the salt. By reabsorption of needed water in the kidney tubules, they discharge a more concentrated urine than do freshwater fishes. Most nitrogenous waste in marine fishes appears to be secreted by the gills as ammonia. Some marine fishes, at least, can excrete salt by clusters of special cells in the gills and intestine.

There are several teleosts—for example, the salmon—that travel between fresh water and seawater and must adjust to the reversal of osmotic gradients. They adjust their physiological processes by spending time (often surprisingly little time) in the intermediate brackish environment.

Marine lampreys, hagfishes, sharks, and rays have osmotic concentrations in their blood about equal to that of seawater so do not have to drink water nor perform much physiological work to maintain their osmotic balance. In sharks and rays the osmotic concentration is kept high by retention of urea in the blood. Freshwater sharks have a lowered concentration of urea in the blood.

Endocrine glands. Endocrine glands secrete their products into the bloodstream and body tissues and, along with the central nervous system, control and regulate many kinds of body functions. Cyclostomes have a well-developed endocrine system, and presumably it was well developed in the early Agnatha, ancestral to modern fishes. Although the endocrine system in fishes is similar to that of higher vertebrates, there are numerous differences in detail. The endocrine glands of fishes are the pituitary, thyroid, suprarenals, adrenals, pancreatic islets, sex glands (ovaries and testes), the inner wall of the intestine, and the ultimobranchial bodies. There are some others whose function is not well understood. These organs regulate sexual activity and reproduction, growth, osmotic pressure, general metabolic activities such as the storage of fat and the utilization of foodstuffs, blood pressure, and certain aspects of skin colour. Many of these activities also are controlled in part by the central nervous system, which works with the endocrine system in maintaining the life of a fish. Some parts of the endocrine system are developmentally, and undoubtedly evolutionarily, derived from the nervous system.

The nervous system and sensory organs. As in all vertebrates, the nervous system of fishes is the primary mechanism coordinating body activities, as well as integrating these activities in the appropriate manner with stimuli from the environment. The central nervous system, the brain, and spinal cord, are the primary integrating mechanisms. The peripheral nervous system, consisting of nerves that connect the brain and spinal cord to various body organs, carries sensory information from special receptor organs such as the eyes, internal ears, nares (sense of smell), taste glands, and others to the integrating centres of the brain and spinal cord. The peripheral nervous system also carries information via different nerve cells from the integrating centres of the brain and spinal cord. This coded information is carried to the various organs and body systems, such as the skeletal muscular system, for appropriate action in response to the original external or internal stimulus. Another branch of the nervous system, the autonomic system, helps to coordinate the activities of many glands and organs and is itself closely connected to the integrating centres of the brain.

The brain

The brain of the fish is divided into several anatomical and functional parts, all closely interconnected but each serving as the primary centre of integrating particular kinds of responses and activities. Several of these centres or parts are primarily associated with one type of sensory perception such as sight, hearing, or smell (olfaction).

Olfaction. The sense of smell is important in almost all fishes. Certain eels with tiny eyes depend mostly on smell for location of food. The olfactory, or nasal, organ of fishes is located on the dorsal surface of the snout. The lining of the nasal organ has special sensory cells that perceive chemicals dissolved in the water such as substances from food material and send sensory information to the brain by way of the first cranial nerve. Odour also serves as an alarm system. Many fishes, especially various species of freshwater minnows, react with alarm to the body fluids produced by an injured member of their own species.

Taste. Many fishes have a well-developed sense of taste, and tiny pitlike taste buds or organs are located not only within their mouth cavities but also over their heads and parts of their body. The barbels ("whiskers") of catfishes, which often have poor vision, serve as supplementary taste organs, those around the mouth being actively used to search out food on the bottom. Some species of naturally blind cave fishes are especially well supplied with taste buds, these often covering most of their body's surface.

Sight. Sight is extremely important in most fishes. The eye of a fish is basically like that of all other vertebrates, but the eyes of fishes are extremely varied in structure and adaptation. In general, fishes living in dark and dim water habitats have large eyes, unless they have specialized in some compensatory way so that another sense (such as smell) is dominant, in which case the eyes will often be reduced. Fishes living in brightly lighted shallow waters often will have relatively small but efficient eyes. Cyclostomes have somewhat less elaborate eyes than other fishes, with skin stretched over the eyeball perhaps making their vision somewhat less effective. Most fishes have a spherical lens and accommodate their vision to far or near subjects by moving the lens within the eyeball. A few sharks accommodate by changing the shape of the lens, as in land vertebrates. Those fishes that are heavily dependent upon the eyes have especially strong muscles for accommodation. Most fishes see well, despite the restrictions imposed by frequent turbidity of the water and by light refraction. Experimental evidence indicates that many shallow-water fishes, if not all, have colour vision and see some colours especially well, but some bottom-dwelling shore fishes live in areas where the water is sufficiently deep to filter out most if not all colours, and these fishes apparently never see colours. When tested in shallow water, they apparently are unable to respond to colour differences.

Colour vision

Hearing. Sound perception and balance are intimately associated senses in a fish. The organs of hearing are entirely internal, located within the skull, on each side of the brain and somewhat behind the eyes. Sound waves, especially those of low frequencies, travel readily through water and impinge directly upon the bones and fluids of the head and body, to be transmitted to the hearing organs. Fishes readily respond to sound; for example, a trout conditioned to escape by the appoach of fishermen will take flight upon perceiving footsteps on a stream bank even if it cannot see the fisherman. Compared with humans, however, the range of sound frequencies heard by fishes is greatly restricted. It is thought that many fishes communicate with each other in a crude way by producing sounds in their swim bladders, in their throats by rasping their teeth, and in other ways.

Other senses (touch, pain, and special senses). A fish or other vertebrate seldom has to rely on a single type of sensory information to determine the nature of the environment around it. A catfish uses taste and touch when examining a food object with its oral barbels. Like most other animals, fishes have many touch receptors over their body surface. Pain and temperature receptors also are present in fishes and presumably produce the same kind of information to a fish as to humans. Fishes react in a negative fashion to stimuli that would be painful to human beings, suggesting that they feel a sensation of pain.

Lateral line system

An important sensory system in fishes that is absent in other vertebrates (except some amphibians) is the lateral line system. This consists of a series of heavily innervated small canals located in the skin and bone around the eyes, along the lower jaw, over the head and down the midside of the body where it is associated with the scales. Intermittently along these canals are located tiny sensory organs (pit organs) that apparently detect changes in pressure. The system allows a fish to sense changes in water currents and pressure, thereby helping the fish to orient itself to the various changes that occur in the physical environment.

EVOLUTION AND PALEONTOLOGY

Although a great many fossil fishes have been found and described, they represent a tiny portion of the long and complex evolution of fishes and knowledge of fish evolution remains relatively fragmentary. In the classification presented in this article fishlike vertebrates are divided into seven classes, the members of each having a different basic structural organization and different physical and physiological adaptations for the problems presented by the environment. The broad basic pattern has been one of successive replacement of older groups by newer, better adapted groups. One or a few members of a group evolved a basically more efficient means of feeding, breathing, swimming, or several better ways of living. These better adapted groups then forced the extinction of members of the older group with which they competed for available food, breeding places, or other necessities of life. As the new fishes became well established, some of them evolved further and adapted to other habitats, where they continued to replace members of the old group already there. The process was repeated until all or almost all members of the old group in a variety of habitats had been replaced by members of the newer evolutionary line.

Early jawless fishes

The earliest vertebrate fossils of certain relationships are fragments of dermal armour of jawless fishes (class Agnatha, order Heterostraci) from the Middle Ordovician Period in North America, about 450,000,000 years in age. Early Ordovician toothlike fragments from the U.S.S.R. are less certainly remains of the class Agnatha. It is uncertain whether the North American jawless fishes inhabited shallow coastal marine waters, where their remains became fossilized, or were freshwater vertebrates washed into coastal deposits by stream action.

Jawless fishes probably arose from ancient small, soft-bodied filter-feeding organisms much like and probably also ancestral to the modern sand-dwelling filter feeders, the Cephalochordata (*Amphioxus* and its relatives). The body in the ancestral animals was probably stiffened by a notochord. Although a vertebrate origin in fresh water is much debated by paleontologists, it is possible that mobility of the body and protection provided by dermal armour arose in response to streamflow in the freshwater environment and to the need to escape from and resist the clawed invertebrate eurypterids that lived in the same waters. Because of the marine distribution of the surviving primitive chordates, many paleontologists doubt that the vertebrates arose in fresh water.

Heterostracan remains are next found in what appear to be delta deposits in two North American localities of Silurian age. By the close of the Silurian, about 400,000,000 years ago, European heterostracan remains are found in what appear to be delta or coastal deposits. In the Late Silurian of the Baltic area, lagoon or freshwater deposits yield jawless fishes of the order Osteostraci. Somewhat later in the Silurian from the same region, layers contain fragments of jawed acanthodians, the earliest group of jawed vertebrates, and of jawless fishes. These layers lie between marine beds but appear to be washed out from fresh waters of a coastal region.

It is evident, therefore, that by the end of the Silurian both jawed and jawless vertebrates were well established and already must have had a long history of development. Yet paleontologists have remains only of specialized forms that cannot have been the ancestors of the placoderms and bony fishes that appear in the next period, the Devonian. No fossils are known of the more primitive ancestors of the agnaths and acanthodians. The extensive marine beds of the Silurian and those of the Ordovician are essentially void of vertebrate history. It is believed that the ancestors of fishlike vertebrates evolved in upland fresh waters, where whatever few and relatively small fossil beds were made probably have been long since eroded away. Remains of the earliest vertebrates may never be found.

By the close of the Silurian, all five known orders of jawless vertebrates had evolved, except perhaps the modern cyclostomes, which are without the hard parts that ordinarily are preserved as fossils. Cyclostomes were unknown as fossils until 1968, when a lamprey of modern body structure was reported from the Middle Pennsylvanian of Illinois, in deposits almost 300,000,000 years old. Fossil evidence of the four orders of armoured jawless vertebrates is absent from deposits later than the Devonian. Presumably they became extinct at that time, being replaced by the more efficient and probably more aggressive placoderms, acanthodians, selachians (sharks and relatives), and by early bony fishes. Cyclostomes survived probably because they early evolved from anaspid agnaths and developed a rasping tonguelike structure and a sucking mouth, enabling them to prey on other fishes. With this way of life they apparently had no competition from other fish groups.

Early jawless vertebrates probably fed on tiny organisms by filter feeding, as do the larvae of their descendants, the modern lampreys. The gill cavity of the early agnaths was large. It is thought that small organisms taken from the bottom by a nibbling action of the mouth, or more certainly by a sucking action through the mouth, were passed into the gill cavity along with water for breathing. Small organisms then were strained out by the gill apparatus and directed to the food canal. The gill apparatus thus evolved as a feeding, as well as a breathing, structure. The head and gills in the agnaths were protected by a heavy dermal armour; the tail region was free, allowing motion for swimming.

Appearance of bone

Most important for the evolution of fishes and vertebrates in general was the early appearance of bone, cartilage, and enamel-like substance. These materials became modified in later fishes, enabling them to adapt to many aquatic environments and finally even to land. Other basic organs and tissues of the vertebrates such as the central nervous system, heart, liver, digestive tract, kidney, and circulatory system undoubtedly were present in the ancestors of the Agnatha. In many ways, bone, both external and internal, was the key to vertebrate evolution.

The next class of fishes to appear was the Acanthodii, containing the earliest known jawed vertebrates, which arose in the Upper Silurian, over 400,000,000 years ago. The acanthodians declined after the Devonian but lasted into the Lower Permian, a little less than 280,000,000 years ago. The first complete specimens appear in Lower Devonian freshwater deposits, but later in the Devonian and Permian some members appear to have been marine. Most were small fishes, not over 75 centimetres (approximately 30 inches) in length.

We know nothing of the ancestors of the acanthodians. They must have arisen from some jawless vertebrate, probably in fresh water. They appear to have been active swimmers with almost no head armour but with large eyes, indicating that they depended heavily on vision. Perhaps they preyed on invertebrates. The rows of spines and spinelike fins between the pectoral and pelvic fins give some credence to the idea that paired fins arose from "fin folds" along the body sides.

The relationships of the acanthodians to other jawed vertebrates are obscure. They possess features found in both sharks and bony fishes. They are like early bony fishes in possessing ganoid-like scales and a partially ossified internal skeleton. Certain aspects of the jaw appear to be more like those of bony fishes than sharks, but the bony fin spines and certain aspects of the gill apparatus would seem to favour relationships with early sharks. Acanthodians do not seem particularly close to the Placodermi although, like the placoderms, they apparently possessed less efficient tooth replacement and tooth structure than the sharks and the bony fishes, possibly one reason for their subsequent extinction.

The first record of the jawed Placodermi is from the Early Devonian, about 390,000,000 years ago. The placoderms flourished for about 60,000,000 years and were almost gone at the end of the Devonian. Nothing is known of their ancestors, who must have existed in the Silurian. The evolution of several other, better adapted, fish groups soon followed the appearance of the placoderms and this apparently led to their early extinction. Their greatest period of success was approximately during the middle of the Devonian, when some of them became marine. As their name indicates (placoderm means "plate skin"), most of these fishes had heavy coats of bony armour, especially about the head and anterior part of the body. The tail remained free and heterocercal (*i.e.*, the upper lobe long, the lower one small or lacking). Most placoderms remained small, 30 centimetres or less in length, but one group, the arthrodires, had a few marine members that reached 10 metres in length. Important evolutionary advances of the placoderms were in the jaws (which usually were amphistylic—*i.e.*, involving the hyoid and quadrate bones) and development of fins, especially the paired fins with well-formed basal or radial elements. The jaws tended to be of single elements with strongly attached toothlike structures. These were too specialized to be considered ancestral to the more adaptable jaws of subsequent bony fish groups. It has been proposed that sharks arose from some group of placoderms near the Stensioelliformes and that the chimaera line (class Holocephali) arose from certain arthrodires; this suggestion, however, is uncertain.

A peculiar, five-centimetre fish, *Palaeospondylus*, from Middle Devonian rocks in Scotland, is probably not a placoderm, although classed with them here. Various suggestions that its relationships are with the agnaths, placoderms, acanthodians, sharks, and even lungfishes and amphibians are unconvincing and its relationships remain completely unknown.

Origin of sharks

Sharks (class Selachii) first appear in the Middle Devonian about 375,000,000 years ago, became quite prominent by the end of the Devonian, and are still successful today. Two Early Devonian orders of primitive sharklike fishes, the Cladoselachiformes and the Cladodontiformes, became extinct by the end of the Permian, about 230,000,000 years ago, while the freshwater order Xenacanthiformes lasted until the Middle Triassic, about 200,000,000 years ago. The final Devonian order, Heterodontiformes, still has surviving members.

Modern sharks and rays arose during the Jurassic Period, about 135,000,000 to 190,000,000 years ago, probably from an older group, the hybodont sharks. Presumably marine cladoselachians gave rise to the hybodont Heterodontiformes during the close of the Devonian. These had the placoderm amphystylic jaws but had paired fins of a more efficient type. In turn the hybodonts are thought to have given rise to the living but archaic mollusk-eating Port Jackson sharks (heterodonts). The relationships of the surviving (but archaic) hexanchiform sharks are unknown. The two main orders of modern Selachii, the Lamniformes (sharks) and Rajiformes (skates and rays), appeared between 140,000,000 and 180,000,000 years ago during the Jurassic Period. They are characterized by a hyostylic jaw (in which articulation involves only the hyoid bone), an

improvement allowing greater mobility of the jaws and an important feature in the methods of predation used by modern selachians.

Skates and rays evolved from some bottom-living shark-like ancestor during the Jurassic. The primary evolution and diversification of modern sharks, skates, and rays took place in the Cretaceous Period and Cenozoic Era. Thus, along with the teleost fishes (discussed below) most surviving sharks, skates, and rays are essentially of relatively recent origin, their main evolutionary radiation having taken place within the last 140,000,000 years.

The class Holocephali, the chimaeras or ratfishes as their modern survivors are called, first appeared in the Upper Devonian but were most common and diversified during the Mesozoic Era. Only one of the seven known orders survived beyond the close of the Cretaccous Period about 65,000,000 years ago. Although not many modern species of chimaeras are known, they are sometimes relatively abundant in their deep-sea habitat. The relationships of these fishes are in question. It has been proposed that they are related to the Devonian ptyctodont arthrodires, which had a chimaera-like shape and pelvic claspers. It has also been suggested that they are closely related to the Selachii because both selachians and holocephalians have many characters in common, such as placoid scales, pelvic claspers, and absence of true bone. It has been suggested recently that both holocephalians and selachians are related to the acanthodians on the basis of the gill arch structures. Further evidence is needed to solve the problem of their classification and relationships.

The class Sarcopterygii are extremely ancient in origin, their first remains appearing in Lower Devonian strata of Germany, about 390,000,000 years old. The most important group, the rhipidistians, which gave rise to the amphibians by the end of the Devonian, became extinct about 120,000,000 years later, near the beginning of the Permian. Two lesser groups, the coelacanths and the dipnoans (lungfishes), have barely survived. Recognition of the class Sarcopterygii is controversial in that some ichthyologists believe that the two major groups, the Crossopterygii (including the rhipidistians and coelacanths) and the Dipnoi, have arisen from independent origins, the present structures of the two groups being widely divergent. The primitive members, however, show several similarities, supporting the view that they had a common ancestor. The nature of the ancestor or ancestors remains a mystery. The Sarcopterygii probably evolved from unknown Silurian jawed freshwater fishes that may also have been ancestral to the actinopterygians.

The rhipidistian crossopterygians apparently flourished in the fresh waters of the Middle Devonian where, in adapting to a habitat subject to seasonal droughts, some evolved pectoral and pelvic appendages strong enough and flexible enough to enable them to leave drying pools to seek out those ponds that retained water. Paradoxically, terrestrial amphibians first rose through the need to survive in water.

The early coelacanths of the Upper Devonian were small freshwater and inshore fishes, and it was not until the Late Permian and Triassic that they became marine and grew larger and more diverse. They are not known as fossils later than the Cretaceous, and it was therefore a great surprise when in 1938 a live, 160-centimetre (63-inch) specimen was taken at 120 metres (approximately 390 feet) off the coast of eastern South Africa.

The dipnoans first appeared in the Lower Devonian and were fully differentiated at that time. They flourished until the close of the Triassic, when their numbers became greatly reduced. The modern Australian lungfish differs little from one of the Triassic forms. The living South American and especially African lungfishes are elongated, specialized fishes adapted to live and survive in more or less annual ponds.

The Actinopterygii, or "ray-finned" fishes, is the largest class of fishes. In existence for about 390,000,000 years, since the Lower Devonian, it consists of some 52 orders containing more than 480 families, at least 80 of which are known only from fossils. The class contains the great majority of known living and fossil fishes, with about 20,000 living species. The history of actinopterygians can be divided into three basic stages or evolutionary radiations, each representing a different level of structural organization and efficiency.

The Chondrostei have a 300,000,000-year history. They Chondrosts

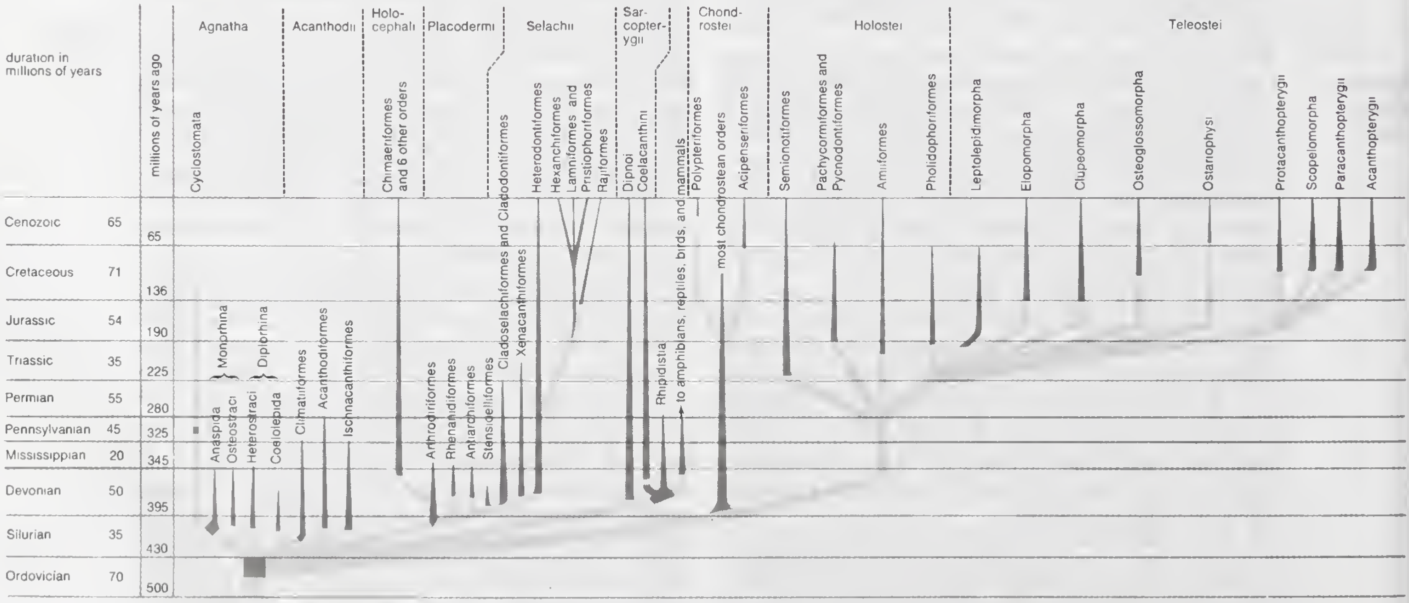

Figure 6: Phyletic family tree for fishes.

arose first in the Lower Devonian, increased in numbers and complexity until about the Permian, and thereafter declined, becoming almost extinct by the middle of the Cretaceous, 100,000,000 years ago. The chondrostean order Palaeonisciformes is the basal actinopterygian stock from which all other chondrosteans and the holosteans evolved. They were the most common fishes of their time, relatively small and typically like later fishes in appearance. In comparison with today's fishes they had peculiar looking jaws and tails. Their tails were heterocercal. On their bodies were thick ganoid scales that abutted each other, rather than overlapping as in most modern fishes. Palaeonisciformes often had large eyes placed far forward, long mouths with the upper jaw firmly bound to the fully armoured cheek, and a relatively weak lower jaw muscle. They gave rise to a great variety of types, with elongate bodies and jaws, bottom-living types that fed on microorganisms, deep-bodied marine reef fishes and coral-eating reef fishes. Almost all of these were replaced by modern teleosts. Surviving Chondrostei are the bottom-feeding marine and freshwater sturgeons, the strange plankton-feeding paddlefishes of the Mississippi of North America and the Yangtze River of China, and the freshwater bichirs and reed fishes (family Polypteridae) of Africa. The relationship of the polypterids is in some doubt, and the group is sometimes placed in the Sarcopterygii.

Several of the chondrostean orders developed characteristics that approached the holostean level of anatomic organization and are sometimes called subholosteans. One of these orders, the Parasemionotiformes, evolved from the Palaeonisciformes in the Lower Triassic and may have given rise to at least some of the holosteans. This evolutionary line leads to the Pholidophoriformes, which gave rise to modern bony fishes, or teleosts.

The holosteans are thought to be of mixed origin and to represent a stage in the evolution of a group of chondrostean orders. If so, the infraclass Holostei does not represent a single lineage. Important holostean characteristics are the approach of the tail toward the homocercal condition and the equal number of fin rays and basal elements of the fin rays. Both of these conditions make the holostean a more efficient swimmer than the chondrostean, as does thinning of the holostean body scales. Another important advance of holosteans was the freeing of the upper jaw from the preopercular bone of the cheek, allowing greater movement of the gill chamber and jaws, with more powerful development of the lower jaw muscle.

Five orders of holosteans are known, with their greatest evolutionary radiation occurring during the Triassic, Jurassic, and Cretaceous periods, when the chondrosteans were declining and the teleosts just beginning to expand. Two holostean groups survive today: the bowfin, *Amia calva*, and the several species of gars, *Lepisosteus*, all found in North America.

Advent of advanced bony fishes

The modern bony fishes, infraclass Teleostei, include the great majority of living fishes. They first appear in the fossil record about 190,000,000 years ago (as the family Leptolepididae) with their homocercal caudal fin and caudal skeleton already fully developed. They arose from an order of holosteans now extinct, the Pholidophoriformes. This group was intermediate in character between the chondrosteans and the teleosts. Teleosts have reached their fullest extent within the last 50,000,000 years and represent a distinct functional advance over their holostean ancestors. They have greater swimming ability, owing to the improvement in the tail structure, and have a still more efficient feeding and gill ventilating apparatus.

The bony fishes represent the culmination of a long evolution toward a body plan with maximum swimming efficiency. Particularly important in this evolution have been changes in fins and in the tail. Some authorities believe that the paired fins arose from a single continuous tail and anal fin that was divided at the vent and extended forward along each side to the head. Later the sections between the pectoral, pelvic, anal, and caudal fins were lost. The fin rays of sharks and rays are of a horny material, but those of many primitive fossil fishes are of bone. The bony fin rays of sarcopterygians and actinopterygians probably arose from scales lying in the fin folds. Modern teleost fishes have flexible fin rays (called soft rays) of jointed segments of bone, or spiny rays, each of solid continuous bone. The first dorsal fin of acanthopterygian fishes is of the spiny type. The original tail fin of primitive fishes was not an effective swimming organ, because of its asymmetry. The steady improvement in tail shape over 400,000,000 years is one of the prominent features of fish evolution. In primitive fishes the tail (vertebral) axis turned upward (heterocercal) or downward (hypocercal) and a lobe of flesh projected from it. This form of tail cannot provide a powerful driving mechanism, because the driving force is unevenly distributed relative to the body axis. With an asymmetrical tail, the fish swims by an undulating motion of the body and tail. In some fishes with a diphycercal tail (with the axis of the vertebrae extending down the middle of the fin lobe), developed in both modern and ancient fishes, the tail remains relatively ineffective because it has remained too rigid for proper propulsive action. The development of a true homocercal tail fin, in which powerful muscles move strong fin rays with a very flexible basal joint and in which the upper and lower lobes are about equal, is a development exclusive to teleost fishes.

Wide variation in form and habitat

As suggested by the existence of more than 400 families, teleosts are extremely varied in anatomical form and in the habitat occupied. They can be divided into about nine superorders, each with distinct evolutionary significance. The Leptolepidimorpha, an extinct, relatively primitive group, has uncertain relationships with other teleosts and is as yet poorly understood. The second group, the Elopomorpha, retains some relatively primitive living members, such as the tarpons, but is mostly represented by the large variety of specialized true eels. The Clupeomorpha includes the herrings and anchovies, relatively primitive fishes, mostly specialized for existence near the surface of the open ocean. A few species are anadromous, breeding in fresh water but spending most of their lives in the sea. The fourth superorder, the Osteoglossomorpha, consists of a group of relatively primitive teleosts, most of which are now extinct. The few surviving members are tropical and worldwide in distribution but adapted for restricted habitats. The Protacanthopterygii is a varied collection of relatively primitive orders, marine, deep-sea, and freshwater in distribution; trouts, smelts, and argentines are examples. The sixth superorder, the Ostariophysi, is an important group of primarily freshwater fishes, including the characins, carps, minnows, loaches, suckers, and catfishes.

The remaining three superorders have a complex fossil history and are not yet fully understood, but all seem to possess similar evolutionary trends. Each group shows a tendency to develop spiny fin rays in the dorsal and anal fins (reduced in some) and a shelf of bone under the eye. There is a tendency for the pelvic fins to move forward on the body, with a reorganization of swimming methods and a slight gain in manoeuvrability. All three groups probably are related and presumably arose from some early protacanthopterygian ancestor. The Scopelomorpha includes a wide variety of deep-sea open-ocean plankton feeders and predators, some of which bear light organs. The Paracanthopterygii is a rather miscellaneous collection of fishes, the most important to man being the cods. The final superorder, the Acanthopterygii, is the result of the great radiation of modern spiny-rayed fishes and contains the dominant fishes in marine shore habitats, tropical, temperate, and Arctic. They also have penetrated the freshwater environment, especially lakes, slow-moving streams, and ponds. The superorder has some important open-ocean members, such as tunas. The key to the successful acanthopterygian radiation probably has been their mobile, protractile mouth.

CLASSIFICATION

Distinguishing taxonomic features. In forming hypotheses about the evolution of fishes and in establishing classifications based on these hypotheses, ichthyologists place special emphasis on the comparative study of the skeleton. There are two primary advantages of this approach. First, direct comparison between extant and fossil groups is possible, the latter usually represented only by bony remains. The second advantage is that the bones of living fishes are relatively easy to observe and to study, compared with other body structures. Proper preservation and special preparation of the nervous system, for example, is difficult and expensive when the fishes compared are from the far ends of the earth. In the study of the relationships of species within a group major use has been made of similarities and differences in the dimensions of external features such as head and body length, and of counts of external characters, such as teeth, fin rays, and scales. Colour pattern is also important. In recent years valuable data on classification of fishes has been obtained from studies of comparative behaviour, physiology, genetics and functional anatomy.

Annotated classification. The following classification has been derived primarily from the works of C. Patterson, Miles, P.H. Greenwood and co-workers, D.E. Rosen and C. Patterson, and K.S. Thomson. Fish classification has undergone major revisions in recent years and further modifications can be expected in the future. Ichthyologists frequently disagree on major as well as minor concepts of phyletic relationships. There remains much to learn about both living and fossil fishes. The geographical distribution given for a poorly known fossil group usually represents only the location of fossil finds not necessarily the true distribution of the group. In the classification presented here groups indicated by a dagger (†) are known only from fossils.

CLASS AGNATHA

Vertebrates with a suctorial or filter-feeding mouth; no true jaws; 2 (possibly 1 sometimes) semicircular canals; pelvic fins lacking, pectoral finlike structures, when present, lacking fin rays; persistent notochord, without bone or cartilage; bony skeleton, when present, formed in skin; true gill arches absent, gill basket present. Habitat of fossil groups uncertain; earliest probably in fresh water.

Subclass Monorhina

With 1 nostril.

†*Order Osteostraci.* Late Silurian to close of Devonian. Heavily armoured with bony plates and scales; bony head shield present; bone cells tend to be absent; pectoral appendages present in some; eyes dorsal, close together; no common gill opening; bottom-dwelling with heterocercal tails. Length about 8–75 cm (roughly 3 to 30 in.).

†*Order Anaspida.* Late Silurian to Late Devonian. Heavily armoured with bony plates and scales; head protected by small bonelike plates; bone cells present; pectoral appendages various, spine or fleshy fold; eyes not close together but facing laterally; no common gill opening; probably swam above bottom with tail lobe extending downward (hypocercal). Length about 10–25 cm (roughly 4 to 10 in.).

Order Cyclostomata (Lampreys and hagfishes). Pennsylvanian and Recent. Freshwater and marine, breeding in fresh water (lampreys); or marine only (hagfishes). Without dermal ossification of any sort; pectoral appendages absent; eyes more or less lateral or dorsal (poorly developed in hagfishes); gill openings multiple, not common; tail more or less diphycercal. Primarily bottom-dwelling fishes, but suctorial, feeding on blood and juices of live fishes (lampreys) or rasping and feeding on flesh of dead or dying fishes (hagfishes); horny teeth present. Length about 15–100 cm (roughly 6 to 40 in.).

†Subclass Diplorhina

With 2 nostrils.

†*Order Heterostraci.* Ordovician to Upper Devonian. Usually heavily armoured, with a head shield in many species and scales or plates; bone cells absent; thin layer of enamel present over bone surface; no paired fins; eyes lateral and far apart; common gill opening present; tail hypocercal. Some perhaps midwater swimmers, others flattened bottom forms. Length about 5 to at least 30 cm (roughly 2 to 12 in.).

†*Order Coelolepida.* Upper Silurian and Lower Devonian. Small, little known agnaths of uncertain affinities. Appear to have had armoured head; body with small bony plates or scales; paired fins uncertain; eyes lateral; gill openings uncertain; number of nostrils uncertain; tail apparently reversed heterocercal. Length up to about 10 cm (roughly 4 in.).

†CLASS ACANTHODII

Jaws apparently formed of the 3rd gill arch (as in all jawed vertebrates) but attached to cranium and hyoid (4th) arch (amphistylic); jaws with teeth; pectoral and pelvic fins present, often with additional paired fins or spines between these; all fins except tail with a strong anterior spine; body covered with bony scales of the ganoid type, with bone cells tending to be lost in some members; no head shields but small dermal plates over head; some known with partially ossified vertebral column; cranium partially ossified; gill opening between jaws and hyoid arch apparently reduced to a spiracle; 3 semicircular canals (as in all higher fishes); an opercle (gill cover) present, attached to hyoid arch, followed by a series of smaller opercles, 1 over each remaining gill opening; caudal fin heterocercal. Active, free-swimming fishes with large eyes placed laterally. Small species probably freshwater, some larger species may have gone to sea.

†*Order Climatiiformes.* Upper Silurian to Lower Carboniferous. With 2 dorsal fins; 2 or more free spines present between pectoral and pelvic fins; operculum not covering entire gill chamber; supplementary operculae present or in some cases operculum covering entire gill chamber; no extramandibular bone. Mostly small, about 10 cm (roughly 4 in.) long.

†*Order Ischnacanthiformes.* Upper Silurian to Middle Carboniferous. With 2 dorsal fins; no free spines between pectoral and pelvic fins; operculum complete; no extramandibular bone.

†*Order Acanthodiformes.* Upper Silurian to Lower Permian. With 1 dorsal fin; no intermediate spines (or with a single pair) between pectoral and pelvic fins; operculum covering all or nearly all of opercular chamber; extramandibular bone present. Length to about 30 cm (roughly 12 in.).

†CLASS PLACODERMI (placoderms)

Jaws amphystylic (supported by both the cranium and hyoid arch); pelvic fins present or absent; pectoral fins or finlike structures often present; often with ossified or partially ossified vertebral column and internal cranium; gill arches present; skeletal ossification reduced in some groups; caudal fin most often heterocercal or some modification of this form. Habitat in many cases uncertain, but apparently most later groups were marine.

†*Order Arthrodiriformes* (arthrodires). Throughout the Devonian, especially common in last half of the period. Head and gill and trunk (thoracic) shields present (the two hinged upon each other in later Devonian forms); entire body more or less fusiform, sometimes flattened; pectoral and pelvic fins usually present and not encased in armour; jaws (when well preserved) of tusklike dermal bony elements. Some early groups freshwater; later groups with giant species (up to 10 m [roughly 33 ft]), marine.

†*Order Rhenanidiformes.* Found throughout the Devonian, but more common in first half of the period. Covered with small bony plates, head shield present in some; body flattened, raylike, with eyes on top of head; gill chambers typically placoderm in occupying a large area below head; pectoral fins greatly enlarged; transverse jaws armed with teeth; apparently primarily marine. Average length about 24 cm (roughly 9½ in.).

†*Order Antiarchiformes* (antiarchs). First known from Middle Devonian, extinct by end of the period. Head and thorax shield present; internal skeleton partially ossified in some; body fusiform but flattened ventrally for bottom living; pectoral fins movable but encased in armour; jaws of small transversely placed bony plates; eyes close together on top of head; well-preserved specimens show intestine with a spiral valve and lunglike structures; apparently mostly small bottom-dwelling freshwater fishes. Length about 10–40 cm (roughly 4–16 in.).

†*Order Stensioelliformes.* Lower Devonian. Not well-known but appearing to have a general lack of bone development, isolated tubercles covering skin in some; gill bars and jaws well developed in reasonably well-preserved specimens; marine. Small; length about 25 cm (roughly 10 in.).

†*Order Palaeospondyliformes.* Middle Devonian. Relationships uncertain, not a typical placoderm. Dermal armour lacking; ring-shaped vertebral centra and neural arches present; jaws apparently present. One genus, *Palaeospondylus,* many specimens, probably of a single species. Length about 4 cm (roughly 1½ in.).

CLASS SELACHII, or CHONDRICHTHYES (sharks, skates, rays, and relatives)

Vertebrates with jaws; dermal and endochondral bone absent, cartilage often calcified but no true bone except possibly at base of teeth and denticles (controversial); scales placoid, of dentine and enamel, present over entire body and enlarged to form teeth on jaws; scales and teeth do not grow once fully formed but are replaced when worn out; notochord often reduced, partially replaced by cartilage, which joins the connective tissue covering of the notochord; labial cartilages present in some; spiracle present (sometimes lost); claspers (pterygopodia) often present in pelvic fins of males, used in mating; intestinal spiral valve present in modern forms (condition in fossils unknown); lungs or structures similar to swim bladders are absent in modern forms.

†*Order Cladoselachiformes.* Middle Devonian to close of Permian. Notochord persistent in adult; 2 dorsal fins; each with a spine; no anal fin; basal cartilages or cartilages of pectoral fin remain along base of fin, radial cartilages unjointed;

pelvic fins without claspers; tail fin externally almost symmetrical but internally heterocercal; jaws amphistylic (upper jaw articulates with cranium and hyoid bone); rostral region of cranium small; postorbital process of cranium large; teeth with 1 large median cusp and smaller lateral cusps; 5 gill openings; marine predators.

†*Order Cladodontiformes.* Middle Devonian to about end of Permian. Notochord persistent in adult; 2 dorsal fins each with or without dorsal spine; anal fin absent; basal cartilage or cartilages of pectoral fin remain along base of fin; radial cartilages unjointed; pelvic fins with claspers; tail fin externally equilobate but internally heterocercal; jaws amphistylic; rostal region of cranium small; postorbital process of cranium large; teeth with 1 large median cusp and smaller lateral cusps; 5 gill openings; marine predators.

†*Order Xenacanthiformes.* Upper Devonian to Middle Triassic. Notochord persistent, but reduced, in adult; some cartilage present; 1 long-based dorsal fin, no spines; postoccipital head spine present; 2 structures similar to anal fins present; basal cartilages of pectoral fins occur in series and enter fin as axial element, radial cartilages unjointed; pelvic fins with claspers; tail fin diphycercal; rostral region of cranium small and postorbital process of cranium large; teeth with a small central cusp and a large lateral cusp on each side; 5 gill openings; freshwater predators.

Order Heterodontiformes. Upper Devonian to Recent. Notochord persistent in primitive forms, replaced partially in advanced ones; 2 dorsal fins, each with a spine; anal fin present; 3 basal cartilages in pectoral fin or a modification of this condition; fin more mobile than 3 preceding orders, radial cartilages of pectoral fins jointed; pelvics with claspers; tail heterocercal or modified from this; jaws remain amphistylic but trend toward hyostylic (supported by movable hyomandibular cartilage); postorbital process of cranium large to reduced; rostral region of cranium usually small; teeth cladodont-like to very modified and rounded; 5 gill openings; marine, several modern forms mollusk eating in habit (heterodonts). Includes the more primitive fossil hybodonts and more specialized, living, heterodonts or hornsharks (Heterodontidae).

Order Hexanchiformes. Jurassic to Recent. Notochord persistent but in some constricted anteriorly; 1 posterior spineless dorsal fin present; anal fin present; basal cartilages of pectoral fin reduced in number; radial cartilages of pectoral fins jointed; pelvic fins with claspers; tail heterocercal to nearly diphycercal; jaws essentially amphystylic but contact with hyoid arch absent in Hexanchidae; postorbital process of cranium reduced; teeth trifid in Chlamydoselachidae, many-pointed in Hexanchidae; 6 to 7 gill openings; marine predators; 2 living families, Chlamydoselachidae (frilled shark) and Hexanchidae (cowsharks).

Order Lamniformes (typical sharks). Lower Jurassic to Recent. Notochord in adults replaced by calcified cartilaginous centra; 2 dorsal fins present, opened or not; anal fin present or absent; 2 basal cartilages of pectoral fin reduced (except Orectolobidae, which has 2); pelvics with claspers, and with basal cartilage; tail heterocercal; jaws hyostylic, mobile, shortened and protrusible; postorbital process of cranium reduced; teeth with varied cusps; 5 gill openings; rostral area elongate; about 15 living families, typical sharks, mostly marine predators, free-swimming and bottom-dwelling, few in freshwater. Length to about 20 m (roughly 66 ft).

Order Pristiophoriformes (sawsharks). Cretaceous to Recent. Like Lamniformes, but with 6 gill openings. Elongated, flattened snout with sawlike teeth along sides in Recent members; body somewhat flattened but elongated; marine shore fishes and in fresh water, tropics. Length (in modern species) to about 1.2 m (roughly 4 ft).

Order Rajiformes (rays, banjofishes, and sawfishes). Upper Jurassic to Recent. Notochord replaced with calcified cartilage; 2, 1, or no dorsal fins; spines absent or present; anal fin absent; pelvic fins with claspers; tail heterocercal to modified, whiplike; jaws modified, supported by pseudohyoid cartilage, very mobile; 5 gill openings; rostral area elongate; marine bottom-dwelling sharklike fishes, flattened; spiracle (lateral opening) used for intake of water to gill chamber; eyes on top of head; gills ventral; greatly enlarged pectoral fins extend forward along gill opening, attached to sides of head and even meet in front of head in some; swim by wavelike motions of pectoral fins; 8 extant families, including Torpedinidae (electric rays). Medium to large fishes; maximum width (in manta ray) to 7 m (roughly 23 ft), weight to 1,700 kg (roughly 3,750 lb); length (in sawfish) to 11 m (roughly 36 ft) with weight to at least 2,500 kg (roughly 5,500 lb).

CLASS HOLOCEPHALI

Jaws holostylic (the palatoquadrate) supporting the upper jaw completely fused to cranium; hyoid arch complete, unmodified; branchial arches below cranium; internal skeleton of cartilage, often calcified but never of bone; dermal skeleton of dentine or dentine-like tissue (placoid scales), never with true bone; scales do not continue to grow once fully formed; pelvic and cephalic claspers in males of some groups.

Order Chimaeriformes (chimaeras). Upper Devonian to Recent. Teeth in a single series of a few tooth plates along each jaw ramus (half); pectoral with 2, and pelvic fins with 1 basal element; pelvic fin claspers present; dermal armour frequently present on head; primitive forms with placoid scales covering body, lost in certain advanced forms; scales specialized in some; dorsal fin spine present or absent; cephalic clasper present in some; marine.

†*Order Copodontiformes.* Devonian to Carboniferous. Known from teeth only; relationship uncertain. Marine.

†*Order Psammodontiformes.* Lower to Upper Carboniferous. Teeth only; little known. Marine.

†*Order Helodontiformes.* Lower Carboniferous to Upper Permian. Teeth numerous, about 10 series on each jaw ramus, some fused into tooth plates; no specialized symphyseal teeth; no cephalic clasper; pelvic claspers unknown; placoid scales cover body; marine.

†*Order Petalodontiformes.* Fossil only; Lower Carboniferous to Upper Permian. Known from teeth only, relationships uncertain; marine; Europe, Asia, North America.

†*Order Edestiformes.* Fossil only; Lower Carboniferous. Known only from specialized symphyseal (fused) teeth; marine; Europe, North America.

†*Order Chondrenchelyiformes.* Lower Carboniferous. Upper jaw with 4 pairs of tooth plates; lower jaw with 3 pairs of tooth plates; dermal plates on skull, cephalic clasper and dorsal fin spine absent, dorsal fin long, continuous along back; marine; known only from Scotland.

CLASS SARCOPTERYGII (fleshy-finned fishes)

Primitive members of the following 2 orders show certain similarities and so are placed together in this class. Some of these similarities are: Heterocercal tail fin with a small amount of fin development above the vertebral column at the posterior end of the tail fin; 2 dorsal fins present; pectoral fins an archipterygium of variable form (an axial median support with side branches); cosmoid scales present, similar to that in acanthodians; modern freshwater forms have lungs; presumably lungs were present in fossil freshwater forms also. Scales grow throughout life of the individual. The internal nares of the Crossopterygii and the Dipnoi may or may not have the same origin.

Order Crossopterygii (coelacanths and fossil relatives). Lower Devonian to Recent. Cranium divided into 2 parts (anterior and posterior) at region for exit of the 5th cranial nerve, these parts movable on each other; choanae (internal nares) present (lost in coelacanths); teeth labyrinthodont (*i.e.*, with complicated unfoldings of the enamel surface); 2 important groups, suborder Rhipidistia, Lower Devonian to Early Permian, mostly shallow freshwater and thought to have given rise to terrestrial vertebrates during the Devonian, and the suborder Coelacanthini. Upper Devonian to Recent, mostly marine, includes the so-called living fossil, *Latimeria chalumnae,* from South Africa, which lacks lungs. Length of rhipidistians to about 3 m (roughly 10 ft); of coelacanths to about 2 m (roughly 6½ ft).

Order Dipnoi (lungfishes). Lower Devonian to Recent. Cranium not divided into movable parts; teeth on upper jaw early reduced and lost in later members; pterygoid bones with fused teeth in plates modified for eating mollusks; 3 surviving types of lungfishes, 1 each in Australia, Africa, and South America. Length 60–200 cm (roughly 24–80 in.).

CLASS ACTINOPTERYGII (ray-finned fishes)

Fins supported by rays of dermal bone rather than by cartilage or cartilage bones. A group of jawed fishes so diverse that no single definition for them can be derived; better understood by determining the distinctive characters of the primitive members and then tracing their various lines of evolution. Primitive actinopterygians can be separated from the sarcopterygians by the following characteristics. Scales ganoid; single dorsal fin; pectoral fins with a series of thin radial bones, rather than basal plates and fleshy lobes; no internal nares. Other important characters: skeleton usually well ossified; scales grow throughout life; swim bladder present (occasionally modified to a lunglike structure).

Infraclass Chondrostei

A mixed group that has undergone many evolutionary diversifications. The remaining orders of the Chondrostei are specialized, often for special habitats and ways of life, but many of the groups show trends toward the holostean level of organization, especially in median fin structure and the development of hemiheterocercal tail in which externally at least the tail appears nearly homocercal.

†*Order Palaeonisciformes.* Lower Devonian to Middle Cretaceous. Mostly fusiform fishes with heterocercal tail; maxillary bone of the upper jaw bound to the preopercle bone space for the muscle restricted to lower jaw, limiting its power and func-

tion; many more fin rays than basal elements in the median fins; 37 families of wide distribution, early members freshwater, later marine.

†*Order Tarrasiiformes.* Carboniferous. Palaeoniscid-like, but with elongate body, a diphycercal tail and dorsal and anal fins continuous with it. One family, Tarrasiidae, Scotland and Illinois.

†*Order Haplolepiformes.* Upper Carboniferous. Peculiar fishes with stout unbranched fin rays; large gular plates; small opercular apparatus. One family, Teleopterinidae; Europe and North America.

†*Order Perleidiformes.* Lower to Upper Triassic. With ganoid scales; fin rays equal number of basal supports rather than exceed them as in Palaeonisciformes and other Chondrostei; tail hemiheterocercal. Three families; worldwide.

†*Order Redfieldiiformes.* Lower and Middle Triassic. Like Perleidiformes but fin rays more numerous than basal elements in dorsal and anal fins. One family, Dictyopygidae, fresh water of South Africa, Australia, and North America.

†*Order Dorypteriformes.* Upper Permian. Similar to Bobasatraniiformes but with very modified skull; scales confined to anterior part of trunk. One family, Dorypteridae; Europe, China.

†*Order Bobastraniiformes.* Lower Triassic. Body deep, laterally compressed; fin rays slightly more numerous than basal supports; opercular apparatus with small opercle, large preopercle; crushing dentition; pelvics absent. Thought to perhaps have been a coral feeder. One family, Bobasatraniidae; marine; widely distributed.

†*Order Pholidopleuriformes.* Lower to Upper Triassic. Some relatively long and slender; dorsal and anal fins far back on body, origin of anal fin anterior to dorsal fin; fin rays more numerous than basal elements; tail hemiheterocercal; jaw support almost vertical or moderately oblique, rather than extremely oblique as in most Chondrostei. One family, Pholidopleuridae; marine and freshwater; wide distribution.

†*Order Peltopleuriformes.* Upper Triassic. Large eyes; hemiheterocercal tail almost symmetrical externally; dentition weak. Two families, Peltopleuridae and Habroichthyidae; marine, perhaps some plankton feeding; Italy, China.

†*Order Platysiagiformes.* Lower Triassic to Lower Jurassic. Elongate, fusiform body, tail hemiheterocercal; median fins holostean, in that rays probably equalled basal elements; teeth large, conical. One family, Platysiagidae; marine; probably predacious; Italy and England.

†*Order Cephaloxeniformes.* Middle to Upper Triassic. Body deep, fusiform; thick head bones and crushing dentition; tail hemiheterocercal. One family, Cephaloxenidae; marine; probably bottom-dwelling mollusk eaters; Italy.

†*Order Luganoiiformes.* Middle and Upper Triassic. Almost holostean in character; body fusiform; head somewhat flattened in the horizontal plane; some head bones fused; jaw suspension inclined forward; fin rays apparently equal to basal elements in number; tail hemiheterocercal. One family, Luganoiidae; marine; probably predacious midwater fishes; Italy.

†*Order Ptycholepiformes.* Middle Triassic to Upper Jurassic. Structure near that of holosteans; fusiform body; fin rays of median fins nearly equalling basal elements in number; jaw support almost vertical; teeth small. One family, Ptycholepididae; marine; presumably plankton feeders; Europe.

†*Order Saurichthyiformes.* Lower Triassic to Upper Jurassic. Elongate, slender; snout elongate; single dorsal fin far back on body, opposite anal fin; tail diphycercal in appearance; number of scale rows reduced, 1 dorsal, 1 ventral, and 1 along each side; jaw suspension almost vertical; teeth large, conical, jaws long. One family, Saurichthyidae; marine and freshwater; predacious; worldwide. Length about 7–150 cm (roughly 2¾ to 60 in.).

†*Order Chondrosteiformes.* Lower Triassic to Upper Jurassic. Body scales and skull bones reduced; snout moderately developed, maxillary and opercular bones reduced; jaw support somewhat inclined backward; median fins paleoniscid-like, rays more numerous than basal supports. Probably gave rise to sturgeons. One family, Chondrosteidae; marine; some were suctorial feeders like sturgeons; England.

†*Order Parasemionotiformes.* Lower Triassic. Very near holosteans in structure but preopercle large and true suborbital bones still present, as in chondrosteans. Two families; marine; Siberia, Greenland, and Madagascar.

Order Acipenseriformes (sturgeons and paddlefishes). Upper Cretaceous to Recent. Almost no internal ossification; scales as large scutes in isolated rows (Acipenseridae); snout enlarged and tactile (Polyodontidae); median fins chondrostean in having more fin rays than basal elements; tail heterocercal. Marine and freshwater, bottom suctorial feeders (sturgeons, Acipenseridae; Europe, Asia, North America) and plankton feeders (paddlefishes, Polyodontidae; China and North America). Length (sturgeons) up to 9 m (roughly 30 ft), weight to 1,400 kg (roughly 3,100 lb).

Order Polypteriformes (bichirs and reedfish). Pleistocene to Recent. Relationships controversial, placed in own subclass by some and thought related to crossopterygians by others. Typical chondrostean characters, such as ganoid scales and a paleoniscoid type of preopercle. Fins modified into long continuous dorsal, tail diphycercal; freshwater; Africa.

Infraclass Holostei

Tail hemiheterocercal; maxillary scale free of preopercle; rays of median fins about equal basal elements in number; spiracle lost; vertebral column tended to increasing ossification; trend toward thinning scales and loss of ganoid layer.

Division Holosteans

Preoperculum intimately bound to and supporting the posterior border of the palate.

Order Amiiformes (bowfin and fossil relatives). Upper Triassic to Recent. Relatively conservative holosteans with typical holostean characters as given above; some specialized in body shape (elongate); most typical fusiform holosteans. One living member of the family Amiidae, with 1 species, *Amia calva* (bowfin), of North America; marine and freshwater, almost worldwide; 6 families.

†*Order Pachycormiformes.* Lower Jurassic to Upper Cretaceous. Long snout, suggesting the teleost swordfishes, Xiphiidae. Two families; Europe and North America.

Order Semionotiformes (gar pikes and fossil relatives). Upper Permian to Recent. Two families of widely divergent fishes; probably independent of the Amiiformes but with typical holostean characters; the fossil Lepidotidae with normal holostean fusiform bodies, which become relatively deep and slab-sided in some members; marine and freshwater, widely distributed. Gar pikes (Lepisosteidae) are elongated, sharp snouted, primarily freshwater predators, still extant in North America; length to about 3.5 m (roughly 11½ ft).

†*Order Pycnodontiformes.* Lower Jurassic to at least Eocene. Very deep bodied, with jaws and teeth modified for nibbling; perhaps fed on coral; marine and widespread.

†*Division Halecostomes*

Holosteans but with a preoperculum not buttressing the bones of the palate.

†*Order Pholidophoriformes.* Upper Triassic to Upper Cretaceous. Difficult to separate from the more primitive of the teleost orders (below). Holosteans with some trends toward teleosts, notably: loss of ganoine from fin rays, scales, and dermal bones; loss of peg and socket joints between scales; loss of bone cells in scales retained in some teleosts; development of intermuscular bones; loss of scalelike bones (fulcra) on leading edges of fins (retained in caudal fin of some teleosts); loss of some skull bones; a "sinking" of skull bones beneath the skin. The caudal skeleton is the major difference between the pholidophoroids and teleosts. Pholidophoroids have the caudal centra incompletely ossified and lack "splint" bones called uroneurals (modified neural arches) that give ridged support to the terminal 4 or 5 vertebrae in teleosts. About 7 families, of which the Jurassic Pholidophoridae are the most likely ancestors of the teleosts; marine and freshwater, of wide distribution.

Infraclass Teleostei (bony fishes)

Tail homocercal; caudal skeleton with perichordally (around the spinal chord) ossified centra; neural arches modified into elongate uroneurals extending forward onto the preural centra, "stiffening" the joints between the terminal 4 or 5 vertebrae. Two hypural bones supporting the lower caudal fin lobe. (Note: Although the above statement can be used to define and separate early teleosts from holosteans, many later groups of teleosts have modified the tail structure greatly, so the definition will not "fit" at first sight. It can be readily shown, however, that all teleosts have a caudal structure derived from that described above.) Teleosts never have ganoid scales; typically, their scales when present are thin, overlapping plates of bone that continue to grow throughout life; their lower jaws lack certain bones found in many chondrosteans or at least have some of these bones fused to single elements.

†*Superorder Leptolepidimorpha.* The recognition of this superorder is highly tentative pending determination of the relationships of these fishes with other teleosts. Sometimes classified with the Halecostomi, these fishes were clearly teleosts in their caudal fin structure. Preopercle supported the palate (as in some holosteans) but with several shifts in this region to a teleost-like preopercular-jaw arrangement and with the adductor muscle of the mandible attached to preopercle; no bone cells in scales; more than 1 supraorbital; gular plate present; apparently no adipose fin; rostral elements with a bone enclosed commissure.

†*Order Leptolepidiformes.* Triassic to Middle or Upper Cretaceous. The characters of the order are those listed above for the superorder. Four families; widely distributed.

Superorder Elopomorpha. A diverse group including very primitive fishes and specialized fishes such as eels and therefore difficult to define. Some primitive members with a gular plate (absent in eels), ethmoid commissure present in some forms in a dermal rostral bone (lost in many eels); a leptocephalus larva; no bone cells in scales of primitive members; pelvic fins abdominal when present.

Order Elopiformes (tarpons, tenpounders, and bonefishes). Upper Jurassic to Recent. Body fusiform, typical fishlike shape; bone-enclosed ethmoid commissure present; roofed post-temporal fossae; primary bite a tongue-parasphenoid type; marine; worldwide in temperate and tropical zones.

Order Anguilliformes (eels). Cretaceous to Recent. Body elongate; fins reduced and gill chamber modified; displaced posterior to much of head; opercular apparatus reduced; pectoral girdle free of skull; caudal and other fins often greatly reduced; bony ethmoid commissure sometimes present; marine and freshwater, worldwide in temperate and tropical regions. Length about 15–300 cm (roughly 6 to 120 in.).

Order Notacanthiformes (deep-sea spiny eels). Middle Cretaceous to Recent. Ethmoid commissure present, like that of elopomorphs; body relatively elongate and tail skeleton reduced; opercular apparatus complete. Three marine, deep-sea families, Halosauridae, Lipogenyidae, and the Notocanthidae (deep-sea spiny eels). Average length about 50 cm (roughly 20 in.).

Superorder Clupeomorpha. Special type of ear–swim-bladder connection present, consisting of a diverticulum of the swim bladder, forming bulla (cavity) within the ear capsule; head lateral line canals on operculum. A diverse group of mostly oceanic, silvery, compressed fishes, many of great commercial importance.

Order Clupeiformes (herrings, anchovies, and allies). Lower Cretaceous to Recent. Characters of the superorder; marine and freshwater, some anadromous; worldwide.

Superorder Osteoglossomorpha. A diverse group of freshwater fishes with a relatively primitive jaw suspension and shoulder girdle. The primary bite of the mouth between parasphenoid and tongue (basihyal and glossohyal); paired rods present, usually bony, at the base of the second gill arch; no bony ethmoid commissure; no leptocephalus larvae.

Order Osteoglossiformes (bony tongues, freshwater butterfly fishes, mooneyes, knife fishes). Middle Cretaceous to Recent. Circumorbital bones well-developed; scales with an irregular reticulated pattern (except Pantodontidae); freshwater, almost worldwide except extremely cold regions. Four families.

Order Mormyriformes (mormyrs). Pleistocene to Recent. With electricity-producing organs; orbital bones reduced; the cerebellum greatly enlarged; swim-bladder–ear connection reduced in adult; sometimes with long snouts for feeding in mud; 2 families, the elephant fishes, Mormyridae, and the Gymnarchidae; fresh water, Africa.

Superorder Protacanthopterygii. A diverse group of relatively primitive teleosts, mostly related by their lack of the specializations (or, in some cases, primitive features) found in the other teleost superorders. Vertebrae usually more than 24; adipose fin present in many members; mesocoracoid bone usually present; glossohyal teeth usually prominent (lost in some); upper jaw usually not protrusible; proethmoid and a series of several perichondral ethmoid commissures; 1 supraorbital bone; no gular plate.

Order Salmoniformes (salmons, trouts, whitefishes, smelts, pikes, and allies). Cretaceous to Recent. Characters are those given for superorder; endochondral ossification often somewhat reduced; marine and freshwater, worldwide. A large and important order, comprising about 35–40 extant and about 6 fossil families. Length about 4–115 cm (roughly 1½ to 45 in.); weight to about 50 kg (roughly 110 lb).

Order Ctenothrissiformes. Mostly Upper Cretaceous, marine fishes of uncertain affinities; possibly close to the basal stock from which the acanthopterygians are derived. The living marine family Macristiidae may belong here.

Order Gonorynchiformes (milkfish and certain deep-sea fishes). Cretaceous to Recent. Toothless; with epibranchial organs and a characteristic caudal skeleton; marine of Indo-Pacific and freshwater of Africa. The anterior ribs and vertebrae show affinities with the superorder Ostariophysi, and the group may belong with the ostariophysans rather than with the Protacanthopterygii. Length about 10–150 cm (roughly 4 to 60 in.).

Superorder Ostariophysi. A group of 5,000–6,000 species, including the majority of known freshwater fishes. Characterized by possession of a Weberian apparatus (a swim-bladder–internal-ear connection with three movable bones).

Order Cypriniformes (characins, tetras, some knife fishes, carps, and minnows). Lower Eocene to Recent. Parietal, symplectic, and subopercular bones present; worldwide in fresh water except Antarctica and Australia. A few North Asian forms enter the sea.

Order Siluriformes (catfishes). Paleocene to Recent. Parietal, symplectic, suboperculum, and true scales absent; often with dermal plates or little bony spines in the skin. Fusion of the supportive parts of the Weberian apparatus extensive. About 30 families; distribution of the superorder primarily freshwater but some families marine, with the majority of the 2,000 species in Africa and South America.

Superorder Scopelomorpha. This superorder, like the Paracanthopterygii and Acanthopterygii (below), is characterized by a tendency toward fin spines, subocular shelves, and separated exoccipital condyles. Scopelomorphs frequently retain such primitive structures as an adipose fin and an asymmetrical caudal fin skeleton.

Order Myctophiformes. Cretaceous to Recent. Characteristics of the superorder. Distinctive jaw musculature, like that of Paracanthopterygii (below). Two subgroups of this order differ in ecology and structure. One contains several families of deep-sea fishes, often elongated predators with large teeth. The second contains benthic fishes, or bottom dwellers (*e.g.*, Aulopidae), tropical inshore fishes (Synodontidae, or lizardfishes), midwater deep-sea fishes with light organs (the large family Myctophidae, or lantern fishes), and bottom-dwelling deep-sea fishes (*e.g.*, Bathypteroidae, or spiderfishes). Order contains about 15 families, worldwide; marine. Mostly small fishes 10–15 cm (roughly 4 to 6 in.); maximum length about 95 cm (roughly 37½ in.).

Superorder Paracanthopterygii. Most with a distinctive type of jaw musculature (involving levitor maxillae superioris muscle and associated structures); caudal vertebrae with the 2nd ural centrum fused with the upper hypural, 2 or fewer epurals and a full neural spine on the 2nd preural centrum; pelvic fins usually placed anteriorly, thoracic (midbody) or even farther forward. In general these fishes have tended to lose primitive acanthopterygian characters.

Order Polymixiiformes (barbudos). Middle Cretaceous to Recent. Barbels suspended from the hypohyal bones (anterior part of the gill arches); spines on the dorsal and anal fins; pelvic fins subthoracic. Retain some primitive paracanthopterygian characters, such as an antorbital bone, a free 2nd ural centrum, 6 autogenous hypurals, 2 uroneurals, and Baudelot's ligament to the 1st vertebra. Adipose fin lacking. Deepwater marine fishes; 1 family, probably only 2 species. Adult length about 30 cm (roughly 12 in.).

Order Percopsiformes (trout-perches, pirate perches, and cave fishes). Eocene to Recent. Mouth gape and buccal dentition reduced; median fin spines reduced or lost; head with spine ornamentation; scale covering of the adipose fin lost. All living species freshwater, North America; length 8–13 cm (roughly 3 to 5 in.). Three extant families, 1 fossil family.

Order Gadiformes. Lower Eocene to Recent. Early gadiforms were similar in structure to early percopsiforms, but almost all remained marine and subsequently specialized into a variety of environments. Reduced caudal skeleton; elongate body; altered head and jaw structure. Primitive gadiforms have 7 branchiostegal rays, primitive percopsiforms 6. All with very reduced fin spines; marine, worldwide. Order includes cods, hakes, cusk eels, pearlfishes, eelpouts, grenadiers, and rattails. Length 7 to about 200 cm (2¾ to 79 in.).

Order Batrachoidiformes (toadfishes). Miocene to Recent. Bottom fishes with short, small, spinous dorsal fins; long soft-rayed dorsal fins; flat heads; 1 family, Batrachoididae; marine, occasionally freshwater, shore fishes of tropics. Length to about 40 cm (15¾ in.).

Order Lophiiformes (goosefishes, anglerfishes, frogfishes and batfishes). Eocene to Recent. Spinous dorsal fin modified as a movable lure. Some deep-sea forms with light organs and males parasitic on females. Marine, widespread; in shallow-water and deep-sea habitats. About 15 families. Length to about 130 cm (51 in.).

Order Gobiesociformes (clingfishes). Recent questionable fossil from Miocene of California. Flattened, depressed fishes with a ventral sucker formed of the pelvic fin and surrounding tissue; no spiny dorsal fin; 1 family, Gobiesocidae; marine and occasionally freshwater in tropics and along many temperate seacoasts.

Superorder Acanthopterygii (spiny-rayed fishes). Spiny fins usually emphasized, rather than reduced (as in paracanthopterygians). Mobile, protractile mouth due to the almost universal lack of the levator mandibula superioris muscle; pectoral fin relatively higher on side of body; Baudelot's ligament almost always attached to basicranium. The 13 orders of the superorder Actinopterygii may be divided into 2 categories (sometimes called series) on the basis of the number of vertebrae, the condition of the fin spines, the position of the pelvic fins, and the presence or absence of ctenoid scales. The series Atherinomopha contains only the order Atheriniformes, the series Percomorpha the remaining actinopterygian orders.

Order Atheriniformes. Eocene to Recent. Fin spines present or absent but frequently weak when present; vertebral number higher than 24; ctenoid scales rare; pelvic fins abdominal, subabdominal, or thoracic in position. Marine shore fishes, also freshwater, tropical and temperate, worldwide. About 16 families, including the oceanic flying fishes (Exocoetidae), killifishes (Cyprinodontidae), live-bearing topminnows (Poeciliidae), and silversides (Atherinidae). Mostly small fishes (2–10 cm [roughly ¾ to 4 in.]) but some needlefishes (Belonidae) to about 130 cm (51 in.).

Order Lampridiformes. Paleocene to Recent. Intermediate in some ways between polymixioids and acanthopterygians, but all living members very specialized. All lack a subocular shelf and pelvic spine; some have a peculiar condition (hypurostegy) in which caudal rays are expanded. Marine, oceanic, tropic, and temperate regions. About 9 families. Medium to large size; to about 2 m (6½ ft) and 300 kg (660 lb) in the opah (Lampridae) and about 10 m (32¾ ft), but far less weight, in the more slender oarfishes, Regalecidae (treated below with the flying fishes and others in the order Atheriniformes).

Order Beryciformes. Squirrelfishes and several deep-sea fishes. Cretaceous to Recent. Spines present in fins; pelvic fins subthoracic; retained primitive number of caudal branched fin rays (17), primitive number of epurals (3); exoccipital condyles poorly developed; orbitosphenoid present. About 15 families of small to medium-sized fishes. Length 5–60 cm (roughly 2 to 23½ in.). Marine, worldwide in tropical and temperate regions (treated below with the flying fishes and others in the order Atheriniformes).

Order Zeiformes (John Dories, boarfishes, and relatives). Lower Eocene to Recent. Anal fin with 1–4 spines; pelvic fin with 1 spine and 5–9 branched rays; caudal fin with less than 15 principal rays; about 6 families, of which the dories, Zeidae, are best known; marine, deep-sea, widespread. Length to about 1 m (3¼ ft) (treated below with the flying fishes and others in the order Atheriniformes).

Order Gasterosteiformes (sticklebacks, tube-snout fish, and sea horses). Eocene to Recent. Frequently with strong spines in dorsal and pelvic fins, spines absent in some; snout often elongated; body often with dermal plates; 9 families, marine and freshwater, widely distributed. Length about 3–200 cm (1¼ to 78¾ in.).

Order Channiformes (snakeheads). Pliocene to Recent. Elongate bodies; dorsal and anal fins present; depressed head with an accessory air-breathing apparatus in the gill chamber. Snakeheads, Channidae; freshwater, tropical Old World. Length about 15–95 cm (6 to 37½ in.).

Order Synbranchiformes (swamp eels). No fossil record. Fins reduced, fin spines absent, pharynx modified for breathing air. Three families, restricted to freshwater, in tropics. Length 20 to about 50 cm (roughly 8 to 20 in.).

Order Scorpaeniformes (scorpionfishes, sculpins, and relatives). Eocene to Recent. A complex group of widely divergent fishes that may be polyphyletic and is difficult to characterize. Three groups may be recognized: scorpaenoid, hexagramoid-cottoid, and anoplopomatoid. United as an order because of a distinctive caudal skeleton and a bony process connecting the 3rd orbital with the preoperculum in most members. Some members with external bony plates. About 21 families; primarily marine, some freshwater, in tropical and temperate regions.

Order Dactylopteriformes (flying gurnards). Pliocene to Recent. Bottom-dwelling shore fishes with dermal armoured plates, movable modified pectoral fin rays. Marine. One family, Dactylopteridae.

Order Pegasiformes (dragonfishes). No fossil record. Bottom-dwelling marine fishes with dermal armour and large pectoral fins. One family, Pegasidae.

Order Perciformes. Upper Cretaceous to Recent. Fins usually with spines; pelvic fin with 1 spine and not more than 5 rays, usually below pectoral fins; caudal fin with 15 rays; no orbitosphenoid, mesocoracoid, or intermuscular bones. An extremely varied assemblage of fishes, with a variety of body plans and other adaptations. About 140 families, divided among about 20 suborders. Mostly marine, worldwide. Size shows broad range; adult length from about 1 cm (less than ½ in.) (certain gobies) to about 4.8 m (15¾ ft) (swordfish); weight to about 900 kg (roughly 2000 lb).

Order Pleuronectiformes (flatfishes). Eocene to Recent. Both eyes on same side of head, skull twisted and asymmetrical, fins usually without spines. Seven families include flounders, soles, and halibuts; mostly marine; bottom fishes, worldwide in tropical and temperate regions.

Order Tetraodontiformes. Eocene to Recent. With a beaklike snout, gill opening restricted to a small opening; probably related to acanthuroids. Eleven families; marine, occasionally freshwater, worldwide in tropics and subtropics. (S.H.W.)

THE PRIMITIVE FISHES (LIVING REPRESENTATIVES)

The jawless fishes: lampreys and hagfishes (Agnatha)

The class Agnatha (phylum Chordata) comprises the jawless, fishlike hagfishes and lampreys and several fossil groups. Hagfishes are minor pests of commercial food fisheries of the North Atlantic, but because of their parasitic habit, lampreys have been a serious pest of food fisheries in the Great Lakes in North America where they have reduced the numbers of lake trout and other species. Agnathans are otherwise of little economic importance. The group is of great evolutionary interest, however, because it includes the oldest known craniate fossils and because the living agnathans have many primitive characteristics.

GENERAL FEATURES

The body of the hagfish is softskinned and nearly cylindrical, with a single nostril at the anterior end, overlying the mouth, and a low caudal fin around the tail. The eyes are vestigial and covered by skin. All of the 20 known species are restricted to cold, marine bottom waters at depths ranging from 10 metres (about 33 feet) in high latitudes to 1,300 metres in equatorial oceans. Adults are 40 to 80 centimetres (15 to 30 inches) long. All species are superficially similar except in the number and position of the gill apertures.

Lampreys

Lampreys, which number about 22 species, are found in cool, fresh, and coastal waters of all continents except Africa. All species are rather similar. The body is smooth and eel-shaped, with well-developed dorsal and caudal fins; the mouth is surrounded by a suctorial oral disk bearing horny teeth. The eyes are well developed, and the nostril is on the top of the head. Adults range from 15 to 100 centimetres long.

Although the gonad of a hagfish usually includes both ovary and testis, there is no evidence either of hermaphroditism (the reproductive organs of both sexes functioning in the same individual) or of self-fertilization. A female produces a small number of tough-skinned, yolk-filled eggs about two centimetres long that hatch into miniature adults.

Hagfishes locate their food by scent. Although some are known to eat fishes immobilized in nets, the best studied species, *Myxine glutinosa,* normally feeds on soft-bodied invertebrates and larger dead animals. *Myxine* burrows into soft marine sediments and rests with only the tip of the head protruding. During respiration, water enters through the nostril and passes by a nasopharyngeal duct to the pharynx and gills. When stimulated by the scent of a dead fish, *Myxine* leaves its burrow and swims against the current. On making contact with the fish, it coils around it and bites into it by protruding and retracting the comblike horny tooth plates on the floor of the mouth. Along each side of the body is a row of prominent glands that produce a distasteful gelatinous slime when the animal is disturbed.

Lampreys mate in a nestlike depression excavated by the male in the gravel bed of a stream; the numerous eggs, about one millimetre (.04 inch) in diameter, lodge in the gravel around the nest. The egg hatches into an ammocoete larva—a blind, wormlike animal that burrows in silt. The larva's mouth is overhung by a hoodlike upper lip that protrudes above the surface of the silt. A continuous stream of water passes in through the mouth and out through the seven pairs of gills. Microscopic plants, the food of the ammocoete, are filtered from the respiratory current by strands of mucus produced by the endostyle, a gland in the floor of the pharynx.

After about three years, when the ammocoete has grown to about 10 centimetres, it undergoes a radical metamorphosis. The eyes complete their development; the upper lip becomes transformed into a suctorial oral disk; the endostyle changes into a thyroid gland; and the fins along the back increase in height. On completion of metamorphosis, a typical lamprey such as *Petromyzon marinus* migrates to the sea, where it feeds by attaching itself with its sucker to bony fishes. It rasps into the flesh with a toothed, tonguelike structure on the floor of the mouth. Saliva containing an anticoagulant facilitates the ingestion of blood and muscle tissue. On attaining full adult size, the lamprey ceases to feed, migrates upstream to a spawning ground, mates, and dies.

Members of several lamprey species do not migrate to sea but feed in fresh water. *Petromyzon marinus dorsatus* once seriously affected commercial fishing in the Great Lakes until measures were undertaken to control it. The brook lampreys do not feed after metamorphosis but mature sexually and reproduce.

From A. Brodal and R. Fange (ed.), *The Biology of Myxine*, Universitetsforlaget, Oslo

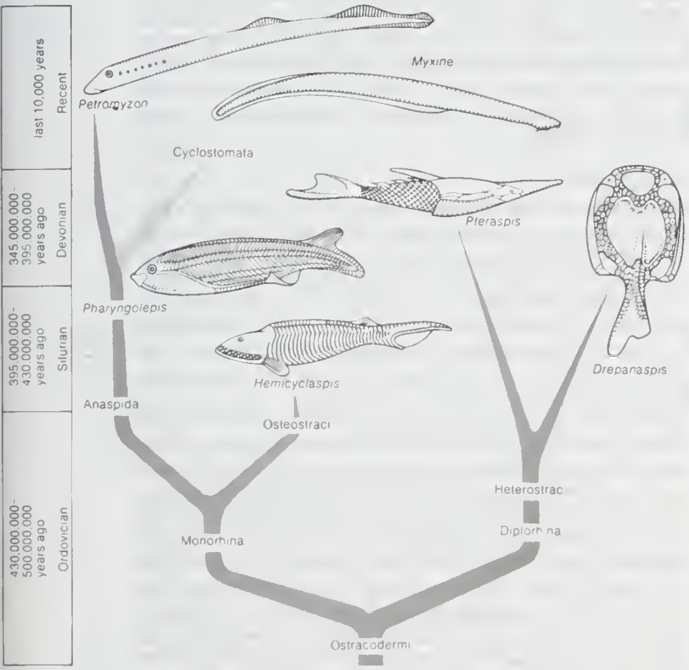

Figure 7: Systematic division of fossil and recent Agnatha.

FORM AND FUNCTION

Variation in body form

The elongated bodies of hagfishes and lampreys are adaptations to a burrowing habit—throughout life in the hagfish, during the larval period in the lamprey. Considerable variation in body form occurs among extinct agnathans. Some Osteostraci, for example, were flattened and, although possessing a powerful swimming tail, appear to have been bottom-dwellers. The size and shape of the mouth suggest that they were filter feeders. The laterally compressed, fishlike form of the anaspids (*e.g.*, *Pharyngolepis*) indicates a free-swimming habit; the absence of fossilized impressions of the mouth region suggests the presence of large suctorial or grasping lips. The extinct heterostracans include obvious bottom-dwellers (*e.g.*, *Drepanaspis*) and others (*e.g.*, *Pteraspis*) that were apparently adapted to mid-water, or nektonic, life. Some heterostracans, for example, had movable enamel plates inside the lower lip, probably to provide a biting or grazing mechanism. Osteostracans, anaspids, hagfishes, and lampreys (Monorhina) have one median nostril, but heterostracans (Diplorhina) appear to have had two, one at each corner of the mouth.

EVOLUTION AND CLASSIFICATION

Evolution. If evidence from fossil and living forms is combined, the Agnatha are distinguishable from the other craniates (Gnathostomata) by what they lack: jaws, lateral fins supported by fin rays, vertebrae, a horizontal semicircular canal in the ear, and genital ducts. The nervous, sensory, endocrine, circulatory, excretory, and muscular systems have the same basic structure as those of gnathostomes but are generally simpler. The presence in the ammocoete larva of an endostyle, a gland that otherwise is found only in protochordates (*e.g.*, amphioxus, tunicates), suggests that the Agnatha represent an evolutionary level intermediate between the protochordates and gnathostomes; but the degree of specialization of known agnathans (particularly the single nostril of most forms) rules out the possibility that they are ancestral to the gnathostomes.

Annotated classification. In the classification below, the groups indicated by a dagger (†) are extinct and known only from fossils.

CLASS AGNATHA

Craniate chordates, lacking jaws; Silurian Period (395,000,000–430,000,000 years ago) to Recent.

Subclass Monorhina

With 1 nostril.

†*Order Osteostraci*

Late Silurian to Late Devonian (345,000,000–395,000,000 years ago); head and gills enclosed in heavy bony shield; nostril between eyes; gill openings ventral; about 7 families.

†*Order Anaspida*

Late Silurian to Late Devonian; active swimmers with tail bent downward; nostril between eyes; gill openings lateral; about 5 families.

Order Cyclostomata (lampreys and hagfishes)

Scales absent, skeleton cartilaginous, horny teeth in mouth, body eel-shaped.

Suborder Myxini (slime eels and hagfishes). Recent; nostril at anterior tip; 5–15 pairs of gills; 2 rows of horny teeth; eyes vestigial.

Family Eptatretidae. Five to 15 gills opening separately to exterior; all oceans except North Atlantic; 2 genera, 13 species.

Family Myxinidae. Five to 7 gills opening by common apertures on each side; all oceans; 4 genera, 8 species.

Suborder Petromyzones (lampreys). Pennsylvanian (280,000,000–325,000,000 years ago) to Recent; dorsal nostril, 7 pairs of gills, horny teeth on oral disk; eyes large, 1 or 2 dorsal fins.

Family Petromyzonidae. Single horny toothplate above the mouth, bearing pointed or rounded teeth; 5 genera, 17 species; Eurasia and North America.

Family Mordaciidae. Two tricuspid teeth above mouth; 1 genus, 4 species; eastern Australia and western South America.

Family Geotriidae. Single horny toothplate above the mouth, bearing 4 spatulate teeth; 1 genus, 1 species; southern Australia, New Zealand, South America.

Subclass Diplorhina

With 2 nostrils.

†*Order Heterostraci*

Ordovician to Upper Devonian (345,000,000 to 500,000,000 years ago); usually heavily armoured; gills with common aperture on each side; length 5–30 cm (2 to 12 in.); about 12 families.

†*Order Coelolepida*

Upper Silurian and Lower Devonian (395,000,000 years ago); a little-known group of unknown affinities; length to about 10 cm; 1 family.

Critical appraisal. Although lampreys have many features in common with the Osteostraci and Anaspida, general disagreement prevails on the classification of the hagfishes. Their affinity with lampreys is questionable, and they should perhaps be removed from the Cyclostomata as a separate order. It has been suggested that the hagfishes are closely related to the heterostracans, but this view is not widely accepted. (Ro.S.)

The cartilaginous fishes: sharks, skates, rays (Chondrichthyes, or Selachii)

The sharks, together with their close relatives, the rays, belong to one of the two great groups of living fishes, the class Chondrichthyes, or Selachii. The latter name is also used for an order that includes only the sharks. Many structural, physiological, biochemical, and behavioral peculiarities make these fishes of particular interest to scientists. The dissection of a small shark is the biology student's introduction to vertebrate anatomy. These fishes are, in a sense, living fossils, for many of the living sharks and rays are assigned to the same genera as species that swam the Cretaceous seas over 100,000,000 years ago. Although by any reckoning a successful group, the modern chondrichthyeds number far fewer species than the more advanced bony fishes, or teleosts; 200 to 250 species of sharks and 300 to 340 species of rays are known.

The danger some sharks and stingrays present to humans makes these animals fascinating and, at the same time, abhorrent. Perhaps for this reason, they figure prominently in the folklore and art of many tropical peoples whose living depends on the sea. The danger from shark attack, while very real, is easily sensationalized, and quite frequently little attempt is made to distinguish between dangerous and harmless species.

GENERAL FEATURES

Problems of taxonomy. The name Selachii refers to a category of fishlike vertebrates, which are given a variety of treatments by ichthyologists. Some consider the Selachii to be a class or subclass comprising all the modern sharks and rays; others restrict the name to an order limited to the modern sharks and certain extinct ancestral forms. Under the latter system, the rays (including the sawfishes, guitarfishes, electric rays, skates, and stingrays) are ranked as a separate order, and the two orders are placed in a class or subclass.

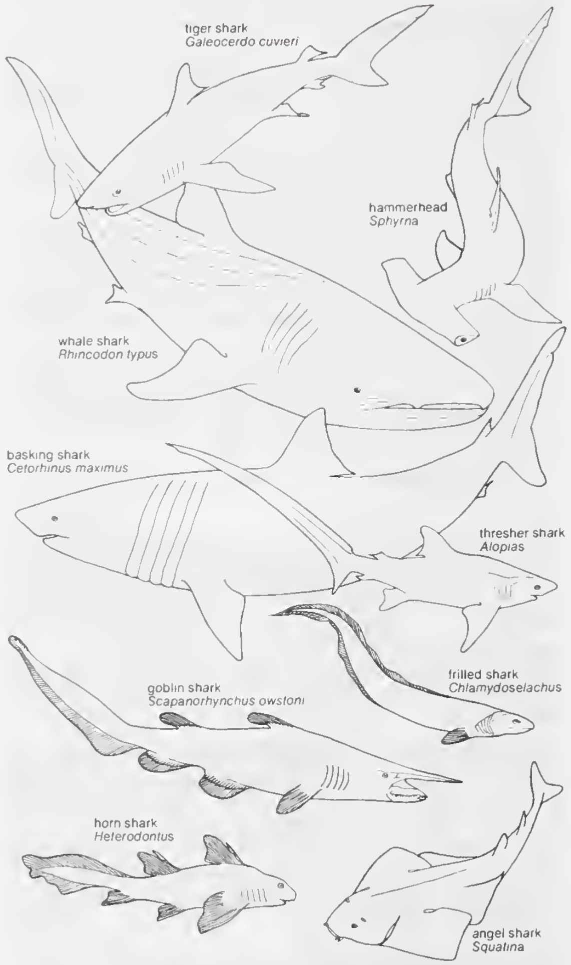

Figure 8: Body plans of representative sharks.

The chimaeras (Holocephali) bear many similarities to sharks and rays; *e.g.,* in skeletal structure, internal organs, and physiology. Ichthyologists commonly, although not unanimously, emphasize these similarities by grouping the modern and ancient sharks, rays, and chimaeras in the class Chondrichthyes, the cartilaginous fishes. Under this system, which is used in the present article, the sharks, skates, and rays are further grouped into one subclass, Elasmobranchii, and the chimaeras into another, Holocephali. (A classification in which the elasmobranchs constitute one class [Selachii] and the chimaeras another [Helocephali] is found above; see *Fishes: a comparative study: Annotated classification.*) Assigning the two groups class rank implies a degree of distinctness equal to that of the amphibians (Amphibia), reptiles (Reptilia), birds (Aves), and mammals (Mammalia).

Distribution and abundance. The majority of sharks and rays are marine fishes, but many enter estuaries; some travel far up rivers, and a few are reported to be permanent residents of freshwater. Most species live in the relatively shallow waters of continental margins or around offshore islands; a few roam far out in the vast spaces of the oceans. Some live at great depths, in midwaters or on the bottom; others are surface swimmers or inhabit the bottom in shallow waters.

Sharks and rays are poorly represented in fish markets of most countries. With limited demand for them, the damage they do to ordinary fishing gear, and the special care required to keep them marketable, fishermen avoid them if possible, or even discard those they happen to catch rather than bring them to port. Consequently, as a source of animal protein sharks and rays are generally underexploited, while the more highly valued bony fishes are generally overexploited. A possible consequence of this may be an increasing prominence of sharks and rays in the marine biota.

IMPORTANCE

Economic uses of elasmobranchs. *Sharks as food.* The meat of sharks is marketed for food in all maritime countries. It may be prepared in various ways—fresh, salted, smoked, or pickled—offered in such forms as steaks, fillets, or flakes and under such names as shark, whitefish, grayfish, swordfish, sea bass, and halibut. The flesh is often rather strong tasting; this quality, however, is one that can be removed by cleaning and washing and soaking the flesh in brine.

Since ancient times, Chinese people have used the dorsal fins of certain sharks and rays as the basis of an epicurean soup. To meet the demand for this product, they have imported fins from far-distant countries. The fins are prepared for market by removing the skin and flesh, leaving only the gelatin-rich cartilaginous rays, which are dried before shipment. Shark liver oil is used in various regions for tanning leather; for preserving wood; as a lubricant; as a folk medicine against rheumatism, burns, and coughs; as a general tonic; as a laxative; and as an ingredient of cosmetics. The liver of a basking shark yields 80 to 600 gallons of oil, which was used in lamps until petroleum products replaced animal oils for illumination. The discovery around 1940 that the liver of the soupfin shark of California is peculiarly rich in vitamin A led to an explosive development of a special fishery in California for this species and a search in other parts of the world for sharks having livers of comparable potency. Within a few years, however, the economic bubble burst, with the invention of a method for manufacturing synthetic vitamin A. The Australian school shark, which was used originally for vitamin A, is now caught for fish fillets.

Other shark products. The hard scales provide an abrasive surface to the skin of sharks and some rays, giving it a special value, as a leather called shagreen, for polishing hard wood. When heated and polished, shagreen is used for decorating ornaments and, in Japan, for covering sword hilts.

Shark leather is made in several countries, including the United States, from the skin of certain shark species after removal of the scales by a chemical process. A luxury product, much more durable than cowhide, shark leather is used for footwear, belts, wallets, and other accessories. The most suitable skins for leather are from tiger, dusky, brown, sand, blacktip, and nurse sharks.

In Greenland some Eskimos make rope from strips of the skin of the sleeper shark. Polynesians once added to the effectiveness of their war clubs with sharks' teeth. Sharks' teeth have some commerical value as curios. The Maori of New Zealand formerly paid high prices for mako sharks' teeth, which they wore as earrings.

Economic value of rays. About 126,000 tons (roughly 110,000,000 kilograms) of rays are marketed for food in various countries about the world, principally in Europe and Asia. By-products in local demand are skins of scaleless species for drumheads; those of scaly species are used for shagreen. Livers are used for oil, fins for gelatin. People of many tropical regions—Polynesia, Oceania, Malaysia, Central America, and Africa—have used the spines of stingrays for such items as needles and awls, spear tips and daggers, and for the poison they contain. The entire tails of stingrays, complete with spines, have been used as whips in various tropical areas.

The electric rays, or numbfish, have little commercial value. The ancient Greeks and Romans used the electric shock of *Torpedo* to relieve diseases of the spleen, chronic headaches, and gout. From the Greek word for electric ray, *narke,* comes the word narcotic. Today these fishes are of interest chiefly as a source of irritation (if not danger) to bathers who step on them and to fishermen who may be shocked when hauling in their wet nets. (L.A.Wa.)

Attacks by sharks

Danger to human life. Among the known shark species, 27 have been authoritatively implicated in attacks on persons or boats. Hospital and other records attest to many attacks on bathers, divers, and people awash in the sea following sea or air disasters. There are also many documented cases of sharks attacking small boats. A number of surviving victims have been able to identify the attacking animal as a shark; a few even reported the type of shark, such as a hammerhead. In many instances, witnesses have seen the assailant clearly enough to determine the species. Fragments of teeth left in wounds of victims or in the planking of boats have often been large enough to provide ichthyologists with the means for precisc identification.

In 1958 the American Institute of Biological Sciences established a Shark Research Panel at the Smithsonian Institution and Cornell University to gather historical and current records of shark attacks throughout the world. For the 35 years from 1928 to 1962, inclusive, the panel listed 670 attacks on persons and 102 on boats. Attacks occur most frequently throughout the year in the tropical zone between 21° north and south of the Equator; from midspring to midfall they extend as far north and south as the 42° parallels. For this reason, it was formerly believed that the most dangerous sharks lived in waters warmer than 21° C (70° F) and that the risk of attack was greatest in the tropics and in the summer months. It is now thought that this circumstance simply results from the fact that more people swim in warm water. It is known, for example, that the most dangerous shark, the white shark, or man-eater (*Carcharodon carcharias*), ranges into the cooler waters of both hemispheres. (L.A.Wa./Ed.)

In Australia, New Zealand, South Africa, and along other coasts heavily infested with sharks, public beaches have lookout towers, bells or sirens, and nets to protect bathers. Since 1937 Australia has used meshing offshore to catch the sharks. Gill nets suspended between buoys and anchors running parallel to the beach and beyond the breaker line have decreased the danger of attack. The nets enmesh sharks from any direction, and although they touch neither the surface nor the bottom, and are spaced well apart, they provide effective control. South Africa has used a similar protection system and has also conducted experiments with electrical barriers.

Sand shark (*Odontaspis taurus*).

The 27 species implicated by the Shark Research Panel in attacks on persons or boats are mostly large sharks with large, cutting teeth. Size, however, is not a dependable criterion, for man-eaters become dangerous when they are about one metre (three or four feet) long; and the largest ones, the basking shark and the whale shark, which grow to 12 and 18 metres (40 and 60 feet), respectively, subsist on minute planktonic organisms and on small schooling fishes. Although either might attack a boat if provoked, only two records of such occurrences have been reported, both in Scotland and both identified with the basking shark. More than 85 percent of all the shark species are too small, too unsuitably toothed, or too sluggish or live at depths too great to be potentially dangerous. The most dangerous sharks include in addition to the white shark, the hammerheads (*Sphyrna*), tiger (*Galeocerdo*), blue (*Prionace*), and sand sharks (*Odontaspis*).

Most stingrays live in shallow coastal waters. Some move with the tides to and from beaches, mud flats, or sand flats. Anyone wading in shallow water where these fishes occur runs some risk of stepping on one and provoking an instant response—the ray lashes back its tail, inflicting an agonizingly painful wound that occasionally leads to fatal complications. Rays can be serious pests to shellfisheries, for they are extremely destructive to oyster and clam beds.

NATURAL HISTORY

Food habits. All sharks are carnivorous and, with a few exceptions, have broad feeding preferences, governed largely by the size and availability of the prey. The recorded food of the tiger shark (*Galeocerdo cuvieri*), for example, includes a wide variety of fishes (including other sharks, skates, and stingrays), sea turtles, birds, sea lions, crustaceans, squid, and even carrion such as dead dogs and garbage thrown from ships. Sleeper sharks (*Somniosus*), which occur mainly in polar and subpolar regions, are known to feed on fishes, small whales, squid, crabs, seals, and carrion from whaling stations. Many bottom-dwelling sharks, such as the smooth dogfishes (*Triakis* and *Mustelus*), take crabs, lobsters, and other crustaceans, as well as small fishes.

The two giant sharks, the whale shark (*Rhincodon typus*) and basking shark (*Cetorhinus maximus*), resemble the baleen whales in feeding mode as well as in size. They feed exclusively or chiefly on minute passively drifting organisms (plankton). To remove these from the water and concentrate them, each of these species is equipped with a special straining apparatus analogous to baleen in whales. The basking shark has modified gill rakers, the whale shark elaborate spongy tissue supported by the gill arches. The whale shark also eats small, schooling fishes.

The saw sharks (Pristiophoridae) and sawfishes (Pristidae) share a specialized mode of feeding that depends on the use of the long, bladelike snout, or "saw." Equipped with sharp teeth on its sides, the saw is slashed from side to side, impaling, stunning, or cutting the prey fish. Saw sharks live in midwaters; sawfishes, like most other rays, are bottom inhabitants.

Thresher sharks (*Alopias*) feed on open-water schooling fishes, such as mackerel, herring, and bonito, and on squid. The long upper lobe of the tail, which may be half the total length of the shark, is used to frighten the fish (sometimes by flailing the water surface) into a concentrated mass convenient for slaughter.

Feeding methods of larger sharks

Most sharks and probably most rays segregate according to size, a habit that protects smaller individuals from predation by larger ones. Even among sharks of a size category, dominance between species is apparent in feeding competition, suggesting a definite nipping order. Other sharks keep clear of hammerheads (*Sphyrna*), whose manoeuvrability, enhanced by the rudder effect of the head, gives them an advantage. When potential prey is discovered, sharks circle it, appearing seemingly out of nowhere and frequently approaching from below. Feeding behaviour is stimulated by numbers and rapid swimming, when three or more sharks appear in the presence of food. Activity soon progresses from tight circling to rapid crisscross passes. Biting habits vary with feeding methods and dentition. Sharks with teeth adapted for shearing and sawing are aided in biting by body motions that include rotation of the whole body, twisting movements of the head, and rapid vibrations of the head. As the shark comes into position, the jaws are protruded, erecting and locking the teeth into position. The bite is extremely powerful; a mako shark (*Isurus*), when attacking a swordfish too large to be swallowed whole, may remove the prey's tail with one bite. Under strong feeding stimuli, the sharks' excitement may intensify into what is termed a feeding frenzy, in which not only the prey but also injured members of the feeding pack are devoured, regardless of size.

In most cases the initial attraction to the food is by smell. Laboratory studies have shown that sharks do not experience hunger in the normal sense of the word, and they are much more prone to be stimulated to feeding by the olfactory or visual cues announcing the appearance of prey.

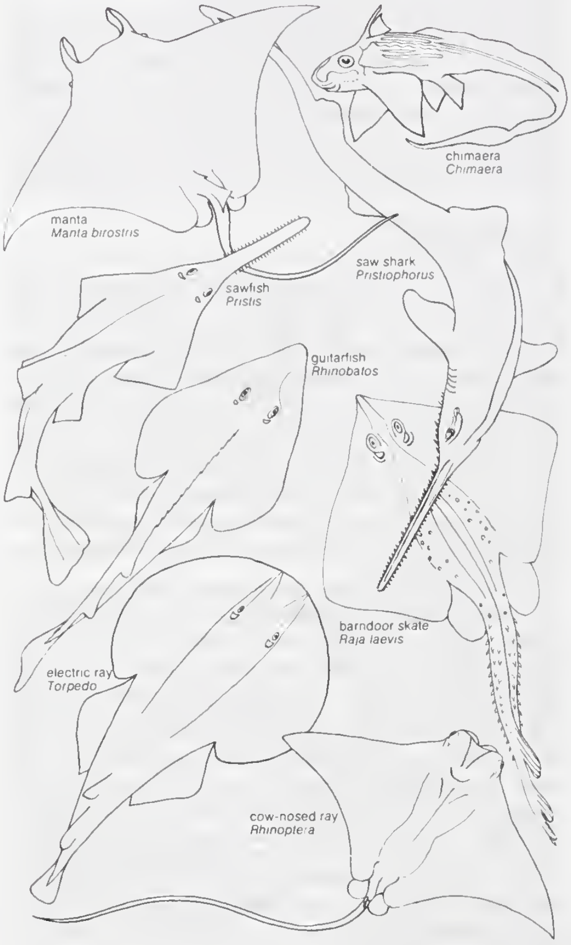

Figure 9: Body plans of representative selachii.

The majority of batoid fishes (members of the order Batoidei; *i.e.*, rays and allies) are bottom dwellers, preying on other animals on or near the sea floor. Guitarfishes (Rhynchobatidae and Rhinobatidae), butterfly rays (Gymnuridae), eagle rays (Mylobatidae), and cow-nosed rays (Rhinopteridae) feed on invertebrates, principally mollusks and crustaceans. Whip-tailed rays (Dasyatidae) use their broad pectoral fins to dig shellfish from sand or mud. Skates (Rajidae) lie on the bottom, often partially buried, and rise in pursuit of such active prey as herring, trapping the victims by swimming over and then settling upon them, a practice facilitated by the skates' habit of hunting at night.

Electric rays (Torpedinidae) are characteristically bottom fishes of sluggish habits. They feed on invertebrates and fish, which may be stunned by shocks produced from the formidable electric organs. With their electricity and widely extensible jaws, these rays are capable of taking very active fishes, such as flounder, eel, salmon, and dogfish. Shallow-water electric rays have been observed to trap fishes by suddenly raising the front of the body disk, while keeping the margins down, thereby forming a cavity into which the prey is drawn by the powerful inrush of water.

Most of the myliobatoid rays (seven recognized families of the suborder Myliobatoidea, which includes all of the typical rays) swim gracefully, with undulations of the broad, winglike pectoral fins. Some species, especially the eagle rays, frequently swim near the surface and even jump clear of the water, skimming a short distance through the air.

Manta, or devil, rays (Mobulidae) swim mostly at or near the surface, progressing by flapping motions of the pectoral fins. Even the largest often leap clear of the water. In feeding, a manta moves through masses of macroplankton or schools of small fish, turning slowly from side to side and using the prominent cephalic fins, which project forward on each side of the mouth, to fan the prey into the broad mouth.

Chimaeras and ghost sharks (Chimaeridae) dwell near the bottom in coastal and deep waters, to depths of at least 2,500 metres (about 8,000 feet). They are active at night, feeding almost exclusively on small invertebrates and fishes.

Reproductive behaviour. Mature individuals of some species of sharks segregate by sex, coming together only during the mating season, when the males, at least those of the larger, more aggressive species, stop feeding. Segregation is a behavioral adaptation to protect the females, one principal courting activity used by the male to induce cooperation of the female in mating being that of slashing her with teeth especially developed for that purpose. After mating, the sexes again separate. The pregnant females also tend to keep apart from the other females of like size. As the time of parturition approaches, the pregnant females move to particular areas, which presumably have properties of environment especially suitable as nursery grounds. When giving birth to their young, they stop feeding, and, soon after parturition is completed, they depart.

Care of the young

Nursery areas vary with species. Some sharks—*e.g.*, the bull and sandbar sharks—use shallow waters of bays and estuaries; the silky shark uses the bottom far out on oceanic banks such as the Serrana Bank in the western Caribbean. The Atlantic spiny dogfish (*Squalus acanthias*) bears its young mostly during the winter far out on the continental shelf of northeastern America almost two years after mating.

A few skates that have been observed mating may be characteristic of other rays. The male seizes the female by biting the pectoral fin and presses his ventral surface against hers while inserting one, or in some species, both claspers into her cloaca. Male skates have one to five rows of clawlike spines on the dorsal side of each pectoral fin. These are retractile in grooves of the skin and are used to hold the female during mating.

The eggs of skates in aquaria have been observed to be extruded in series, usually of two but sometimes one, with rests of one to five days between extrusions. A female of a European skate, *Raja brachyura,* laid 25 eggs over a 49-day period in the aquarium located at Plymouth, England.

Although the mating of chimaeroids has not been observed, it is generally presumed that the mode of copulation is similar to that of sharks and that the male's frontal spine and anterior appendage of the pelvic fins are probably used in securing the female. Two eggs are laid simultaneously, one from each oviduct. They are often carried for a relatively long period before being laid, several hours or even days, each protruding for the greater part of its length.

FORM AND FUNCTION

Distinguishing features. The elasmobranchs are fishlike vertebrates differing from bony fishes in many respects. The skeleton is composed of cartilage and, although partly calcified (especially in the vertebrae), lacks true bone.

Shark scales

There are five to seven fully developed gill clefts, opening separately to the exterior. Most sharks and all rays have an opening behind each eye, called a spiracle, which is a modified first gill cleft. The dorsal fin or fins and fin spines are rigid, not erectile. Scales, if present, are structurally minute teeth, called dermal denticles, each consisting of a hollow cone of dentine surrounding a pulp cavity and covered externally by a layer of hard enamel-like substances called vitrodentine. The scales covering the skin do not grow throughout life as they do in bony fishes, but have a limited size; new scales form between existing ones as the body grows. Certain other structures, such as the teeth edging the rostrum (beak) of sawfishes and saw sharks, the stinging spines of sting rays, and the teeth in the mouth, are structurally modified scales. The teeth, arranged in rows in the mouth, are not firmly attached to the jaws but are imbedded in a fibrous membrane lying over the jaws. When a tooth becomes broken, worn, or lost, it is replaced by one moving forward from the next row behind; at the base of the innermost row are rudimentary teeth and tooth buds that develop and move forward as needed. A spiral membranous fold (spiral valve) extends through the intestine of all sharks, rays, and chimaeras.

The rays differ externally from sharks in having the gill openings confined to the lower surface; the eyes of the rays are on the dorsal surface, and the edges of the pectoral fins are attached to the sides of the head in front of the gill openings. Some rays lack scales, and others are variously armed with thorns, tubercles, or prickles, all of which are modified scales; the tails of some have long, saw-toothed spines equipped with poison glands. In the sawfishes the snout is prolonged into a long, flat blade armed on either side with teeth. Some skates and a few rays have electric organs by which they can administer electric shocks to enemies or prey.

The chimaeras have only one external gill opening. In the adult the skin on each side of the head is smooth and lacks scales; the teeth consist of six pairs of grinding plates. The dorsal fin and spine are erectile. Like male sharks and rays, male chimaeras have claspers that serve to transfer sperm to the female, but, in addition, they have an erectile clasping device, the tantaculum, in front of each pelvic fin; most species have another such organ on top of the head.

Senses. Although sharks are often said to have a low order of intelligence, they, as well as rays and chimaeras, have survived successfully over a long period of geologic time. They are well equipped to locate prey and their own kind; to direct the course of their seasonal migrations; to discriminate specific localities; to respond to variations of temperature; to react to attractive or repelling substances in the water; and perhaps even to feel objects some distance away from them. They can see, hear, smell, taste, feel, and maintain their equilibrium. The roles of the sense organs have been studied in only a few species, principally sharks, and consequently remain imperfectly understood.

The sense of smell is highly developed and probably the principal means of locating prey and guiding the predator toward it. Given a favorable direction of current, sharks can detect incredibly minute concentrations—fractions of a part per million (*i.e.*, less than 1×10^{-6} parts)—of certain substances in the water, such as blood.

Although their eyes are structurally and functionally adapted for seeing, it is believed that their visual acuity in discerning the form and colour of an object is limited. The importance of sight relative to smell increases as a shark approaches its target.

The hearing apparatus, located in the auditory capsule of the cranium, includes a system of semicircular canals, which are responsible for maintaining equilibrium. Sharks seem to be remarkably sensitive to sounds of low frequency and to possess extraordinary faculty for directional hearing. Whether or not hearing is more sensitive than smell has not yet been established.

Sensory organs identified as taste buds are located on the floor, sides, and roof of the mouth and on the throat, as well as on the tongue. Experiments on several species of large sharks indicate that they do discriminate food types, preferring tunas, for example, to other fish species. Under some conditions, however, they become less fastidious, going into a feeding frenzy in which they attack anything, including others of their own kind.

Sensory organs located in the skin of all sharks, rays, and chimaeras receive a variety of information—vibrations of low frequencies, temperature, salinity, pressure, and minute electrical stimuli, such as are produced by another fish in the vicinity. These organs are located in the lateral line system (a series of sensory pores along the side), in groups of pores on the head (ampullar organs), and in pit organs distributed on the back, flanks, and about the jaws.

The urea retention habitus

Salt and water balance. Most marine vertbrates maintain lower concentrations of salts and other chemicals in their blood than are found in seawater, and so face a continuous problem of water loss to the environment, because of the tendency of water to move through membranes from regions of low salt concentration to regions of higher concentration. The marine cartilaginous fishes differ from almost all of the bony fishes (except the coelacanths and aestivating lungfishes) in being able to reabsorb in the renal (kidney) tubules most of their nitrogenous waste products (urea and trimethylamine oxide) and to accumulate these products in their tissues and blood, an ability termed the urea retention habitus. The concentration within the body thus exceeds that of the surrounding seawater, and water moves into the body with no expenditure of energy. When any of these fishes moves into freshwater, as many do, the urine flow to the outside increases; hence, the concentration of urea in the blood decreases. In the sawfish, for example, the increase of urine output is more than twentyfold; the blood urea concentration decreases to less than one-third the amount observed in marine forms. Purely freshwater elasmobranchs, such as the stingrays of the Orinoco and Amazon drainage systems, seem to lack the urea retention habitus.

Respiration. Sharks with spiracles take in some water through them, but they breathe chiefly by opening the mouth while expanding the mouth-throat (bucco-pharyngeal) cavity and contracting the gill pouches to close the gill slits. With the mouth closed, they contract the bucco-pharyngeal cavity while dilating the gill pouches, thus drawing the water over the gills where the exchange of oxygen and carbon dioxide takes place. Then, with the mouth still closed, they contract the bucco-pharyngeal cavity and gill pouches and open the gill slits to expel the water. Most of the rays, on the other hand, take in water chiefly through the spiracles; these then close by contraction at their anterior margins, which bear rudimentary gill filaments and a spiracular valve. Folds of membrane on the roof and floor of the mouth prevent the water from passing down the throat and direct it to the gill openings. Skates, which usually hold the lower surface of the head slightly above the bottom, inhale some water through the mouth; mantas, which have small spiracles and live near the surface, respire chiefly through the mouth. Skates, stingrays, guitarfishes, and angel sharks frequently reverse the direction of flow through the spiracles, apparently to clear them of foreign matter. Chimaeras take in water chiefly through the nostrils, keeping the mouth closed for the most part. The water reaches the mouth primarily through grooves leading there from the nostrils.

Reproduction and development. All species of sharks, rays, and chimaeras produce large, yolk-rich eggs. These are fertilized internally, for which the males are equipped with two copulatory organs called claspers along the inner edges of the pelvic fins. Each clasper has a groove for guidance of sperm. The few published descriptions of mating sharks and rays are probably characteristic of the entire group. The male grasps one of the female's pectoral fins with his teeth to hold her in position as he inserts a clasper through a cavity (cloaca) and into a tube (oviduct). Males of most species probably use only one clasper at a time. The sperm travel to the anterior end of the oviduct, where they fertilize the eggs. The eggs then move down the oviduct past the shell gland, where they are covered by a shell or capsule.

In oviparous (egg-laying) species, which include some of the sharks, probably all the skates, possibly some of the guitarfishes, and all of the chimaeras, the eggs are en-

Egg characteristics

veloped in a horny shell, usually equipped with tendrils for coiling around solid objects or with spikelike projections for anchoring in mud or sand. The egg cases of most species are more or less pillow-shaped; those of the horned sharks (Heterodontidae) are screw-shaped with a spiral flange. The eggs of chimaeras are elliptic, spindle-shaped, or tadpole-shaped and open to the exterior through pores and slits that permit entrance of water during incubation. An egg of the whale shark found in the Gulf of Mexico measured 30 centimetres (12 inches) long by about 14 centimetres ($5\frac{1}{2}$ inches) wide and was eight centimetres (three inches) thick. Protected by the shell and nourished by the abundant yolk, the embryo of an oviparous species develops for $4\frac{1}{2}$ to $14\frac{3}{4}$ months before hatching.

The majority of sharks and most, possibly all, rays other than the skates are ovoviviparous (*i.e.*, the egg hatches within the mother). In this case, the egg is first coated in the shell gland with a temporary membranous capsule that lasts only during early development. After emerging from its capsule, the embryo remains in the oviduct of the mother, nourished by the yolk sac to which it remains attached. Embryos of some ovoviviparous sharks, notably the porbeagle (*Lamna nasus*), mako (*Isurus oxyrinchus*), and sand shark (*Odontaspis taurus*), ingest yolks of other eggs and even other embryos within the oviduct of the mother after the contents of their own yolk sacs are exhausted. In the majority of ovoviviparous sharks and rays, organically rich uterine secretions provide supplemental nourishment, which is absorbed by the yolk sac and in many cases by appendages borne on its stalk. In some genera of rays, vascular filaments producing these secretions extend through the spiracles and into the digestive tract of the embryos.

Several shark species are viviparous—*i.e.*, the yolk sac develops folds and projections that interdigitate with corresponding folds of the uterine wall, thus forming a yolk placenta through which nutrient material is passed from the mother.

Growth. Growth of a few shark species has been measured or estimated by the differences in length at the times of tagging and recapturing specimens, by statistical analysis of length in systematically collected samples, by the space between concentric circles on the centra of the vertebrae, and by periodic measurements of specimens kept in aquariums. All studies indicate a slow growth rate. During the 10 years between birth and maturity, male Atlantic spiny dogfish grow an average of 47 centimetres (19 inches) and females 67 centimetres (26 inches). The Greenland shark (*Somniosus microcephalus*), which attains $6\frac{1}{2}$ metres (21 feet) or more (although rarely taken larger than about four metres [13 feet]), grows only about $7\frac{1}{2}$ millimetres (a little more than $\frac{1}{4}$ inch) per year. The annual growth increments of tagged juvenile whitetip reef and Galápagos sharks, both species that become at least $2\frac{1}{2}$ metres (eight feet) long, were found to be 31 to 54 millimetres (just over one to two inches) and 41 millimetres (about $1\frac{1}{2}$ inches), respectively. The Australian school shark (*Galeorhinus australis*) grows about 80 millimetres (three inches) in its first year and 30 millimetres (one inch) in its 12th year. By its 22nd year, it is estimated to be approaching a maximum length of 160 centimetres (just over five feet).

The disk of the eastern Pacific round stingray (*Urolophus halleri*) increases in width on the average from 75 millimetres (three inches) at birth to 150 millimetres (six inches) when mature, when 2.6 years old. In the next five years it grows about 60 millimetres (about $2\frac{3}{8}$ inches) more toward its maximum recorded width of 25 centimetres (10 inches) in males or 31 centimetres ($12\frac{1}{4}$ inches) in females. The males of European thornback rays (*Raja clavata*) are about 50 centimetres (20 inches) wide when they reach first maturity, about seven years after birth; females are 60 to 70 centimetres (24 to 28 inches) at first maturity, nine years after birth.

EVOLUTION AND CLASSIFICATION

Evolution. The earliest fossil remains of fishlike vertebrates are too fragmentary to permit tracing the modern fishes precisely to their origins. It is believed that the ancestral forms evolved during the Silurian Period (from about 430,000,000 to 395,000,000 years ago) in the upper reaches of streams. During the end of the Silurian and the beginning of the Devonian that followed, there appeared an exceedingly diverse group of armour-plated fishes with jawlike structures, paired fins, and bony skeletal tissue. Paleontologists refer to these extinct forms as a distinct class, Placodermi. Between the beginning and end of the Devonian (the latter about 350,000,000 years ago), the placoderms reached their peak in diversity and numbers and almost completely died out; only a few lingered another 10,000,000 years into the Early Mississippian (roughly, the Lower Carboniferous). During their flowering, the placoderms evidently gave rise to the Osteichthyes (the bony fishes) and the Chondrichthyes (the cartilaginous fishes). Even though the lines of evolution remain to be discovered, it seems quite clear that the two groups evolved independently, the Chondrichthyes appearing much later than the Osteichthyes.

Relationship to bony fishes

Although a few sharklike forms remained in fresh water, the vast majority soon invaded the sea, perhaps in response to the arid Devonian climate. There they adapted to life in salt water by evolving the urea retention habitus (see above *Salt and water balance*). Their cartilaginous skeleton, far from representing an evolutionary stage antecedent to the Osteichthyes, as was once believed, is more than likely degenerate rather than primitive. Possibly their precursors were the petalichthyids, a group of Devonian sharklike placoderm fishes that had ossified skeletons and well-developed fins.

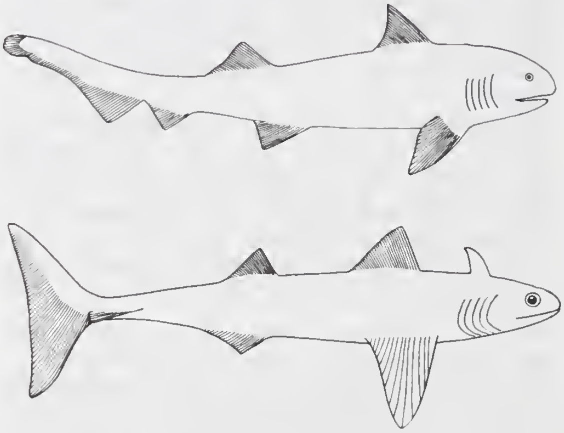

Figure 10: *Primitive sharklike fishes.*
(Above) *Hybodus* from the Mesozoic Era. (Below) *Cladoselache* from the Late Devonian Period.

The phyletic relationship of the chimaeras and the sharks and rays is a subject capable of varying interpretation. Although both groups have many characteristics in common, such as the possession of a cartilaginous skeleton, placoid scales, teeth simply embedded in gums, a spiral valve in the intestine, urea retention habitus, internal fertilization (for which the males have claspers), and the absence of a swim bladder, the two groups may have evolved independently along parallel lines, the chimaeras from the pyctodonts, an order of Devonian placoderms with body form and tooth structure very suggestive of modern chimaeras.

Fossil sharklike fishes

The first fishes clearly identified with the Chondrichthyes were sharklike in form. One order, the Pleurocanthodii, consisting of one family of freshwater, sharklike fishes, appeared in the Late Devonian, was abundant in the Carboniferous and Early Permian (until about 250,000,000 years ago), and disappeared during the Triassic Period, which followed. These fishes were characterized by the following features: the skeletal structure of both pectoral and pelvic fins had an axis with side branches (called the archipterygial type); the tail was almost symmetrical, being only slightly tilted upward; a long movable spine projected backward from the back of the head; the teeth had two divergent prongs and a central cusp set on a buttonlike base; the anal fin was two-lobed; and the males had claspers.

The other order, Cladoselachii, consisted of marine fishes known only from fossils of the late Middle Devonian, Carboniferous, and Early Permian periods. Their distinguishing characteristics were that each tooth had a long base composed of a bonelike tissue, from which rose three conical cusps, a tall central one and two smaller ones on either side; the body scales had several lobes or cusps; the jaws had double articulation, extending forward to the snout; claspers were lacking; the outline of the caudal (tail) fin was almost symmetrical but with differing internal structure of the upper and the lower lobes.

The cladoselachians were probably ancestral to a group closer to modern sharks, the order Hybodontii. They probably represent an intermediate state in selachian evolution and are classified by some authorities in the order Selachii. Although the jaws had the primitive double articulation, the skeletal support of the pectoral and pelvic fins was close to that of modern selachians, with basal elements projecting outward into the fins. The teeth near the front of the mouth were generally sharp-cusped; the cusps of those further back were sometimes reduced to a rounded crown. The front teeth were suitable for seizing prey; those in the back were suitable for crushing mollusks. The hybodonts appeared toward the end of the Devonian, flourished in the Late Paleozoic, and died out during the latter half of the Mesozoic, a few lasting into the Late Cretaceous (about 80,000,000 years ago).

The great period of radiation (diversification) in marine vertebrates characterizing the Mesozoic ended in the Permian, and the chondrichthyed fishes, which had reached their greatest flowering during the Carboniferous, became greatly reduced, remaining so until the Jurassic (about 190,000,000 years ago), when the areas of the seas expanded and those of the land diminished. Then the six-gilled shark (*Hexanchus*), horned shark (*Heterodontus*), and guitarfishes appeared. By the end of the Cretaceous, most of the families and many genera of modern sharks, as well as those of skates and rays, were represented. The evolution of elasmobranch fishes, much as they are known today, had been accomplished.

Annotated classification. The most recent approaches to a comprehensive review of the chondrichthyeds are that of the American ichthyologists H.B. Bigelow and W.C. Schroeder and that by the American paleontologist Alfred S. Romer. The following synopsis, based on their work, provides principal identifying characteristics of all major Recent groups.

CLASS CHONDRICHTHYES (or SELACHII)

Subclass Elasmobranchii (sharks and rays)

Chondrichthyeds with 5–7 pairs of gill clefts not covered by a fold of skin, opening separately to the exterior.

Order Selachii (sharks)

Elasmobranchs with gill clefts opening at least partly on the side of the body.

Suborder Notidanoidei. Sharks having 6 or 7 gill openings. Anal fin present.

Family Hexanchidae (cow shark and 7-gilled sharks). Lower Jurassic to present; marine. The cow shark (*Hexanchus griseus*), in deep water, down to 1,875 m (about 6,000 ft). Distinguished by presence of 6 gill slits; teeth of lower jaw strikingly unlike those of upper, the 5 or 6 on either side of the central tooth being about twice as broad as high, their inner edges saw-toothed with 5–8 pointed cusps. Size up to at least 5 m (about 16½ ft), estimated length at maturity about 2 m (about 6½ ft). Ovoviviparous; 4.5-m (15-ft) specimen contained 108 embryos. The 7-gilled sharks (*Heptranchias* and *Notorhynchus*) are widely distributed in warm and temperate continental waters.

Suborder Chlamydoselachoidei

Family Chlamydoselachidae (frilled shark). Miocene to present. One modern species known, rather rare. Distinguished by 6 gill slits, the margins of the first being continuous across the throat. Size to about 2 m (about 6½ ft). Moderately deep water of the eastern North Atlantic from Portugal to Norway and in the North Pacific off California and Japan.

Suborder Heterodontoidei. Upper Devonian to present. Five gill openings on each side of body; anal fin present; 2 dorsal fins, each preceded by a spine. Marine.

Family Heterodontidae (Horned sharks, bullhead, Port Jackson shark). With 1 Recent genus and about 10 species. Oviparous; egg case screw-shaped; a double spiral flange extending from apex to large end. Teeth in upper and lower jaws alike, those in front incisor-like, those on sides much larger and molar-like. Bottom dwellers out to about 180 m (about 590 ft) depth. Australia, New Zealand, East Africa, East Indies, China, Japan, eastern Pacific, north as well as south. Not known in Atlantic or Mediterranean. Size up to about 1.4 m (about 4½ ft).

Suborder Galeoidei (typical sharks). Five gill openings on each side of body; anal fin present; dorsal fin or fins not preceded by spines.

Family Odontaspididae (formerly *Carchariidae;* sand sharks). Upper Jurassic to present. Marine. Caudal peduncle (narrow "stalk" of the tail) without lateral keels; with a distinct pit on its upper surface but none on its lower. Teeth large, slender, smooth-edged, lower eyelid without a nictitating membrane (a transparent extra eyelid). Development is ovoviviparous; maximum size varies with species, from around 2.8 to 6 m (about 9 to 20 ft). One recent genus (*Odontaspis*) recognized, with some 6 species, found in warm temperate and tropical coastal waters of all oceans. Frequent shallow water near shore; sluggish except when feeding.

Family Scapanorhynchidae (goblin sharks). Lower Cretaceous to present. Marine. One genus, known from Japan, Portugal, and India, perhaps from Australia. Prominent elongation of the snout; protruding jaws. Maximum size to about 3.4 m (about 11 ft). Probably ovoviviparous. A deepwater shark, fished commercially in Japan for its liver and flesh.

Family Isuridae. Upper Cretaceous to present. Three genera, marine, although at least 1 species (the white shark) occasionally strays into estuaries. Distinguished by 2 dorsal fins, of which the first is much larger than the second and the rear end of its base situated well in advance of the pelvic fins; caudal fin lunate (crescent-shaped), its axis steeply raised. Teeth large. Ovoviviparous or viviparous. Circumglobal, occurring in boreal to warm temperate belts of all oceans in both hemispheres. Size in the great white shark (*Carcharodon carcharias*) varies from 1.4 to 6 m (4.6 to 19.7 ft) in length, but individuals may possibly exceed 8 m (26.2 ft). Three genera, *Lamna, Isurus,* and *Carcharodon.* the last 2 dangerous to man, the great white shark unquestionably the most dangerous of all fishes.

Family Cetorhinidae (basking shark). Oligocene to present. Marine. Two dorsal fins, the first well in advance of pelvics; lunate caudal fin; gill openings extending around sides almost meeting at throat. Hundreds of minute teeth. Ovoviviparous. Embryonic development undescribed. Size at birth probably 1.5–1.8 m (5–6 ft); maximum size to 13–14 m (42½–46 ft). Single genus (*Cetorhinus*) inhabiting temperate and boreal zones around the world. Whether basking sharks of the Northern and Southern hemispheres belong to a single species (*C. maximus*) is undetermined. Sluggish, inoffensive sharks, living at or near the surface, feeding wholly on plankton, which they sieve out of the water with their gill rakers.

Family Alopiidae (thresher sharks). Eocene to present. One genus, 5 species. Distinguished by the elongated upper lobe of the tail fin, which is almost as long as the rest of the body. Teeth small, bladelike. Ovoviviparous. Total length to about 6 m (20 ft). Cosmopolitan at low and middle latitudes of all oceans. Harmless to man. Occasionally sold for food.

Family Orectolobidae (carpet and nurse sharks, wobbegongs). Upper Jurassic to present. Marine. Distinguished by the presence of 2 dorsal fins, the origin of the first over or behind the pelvic fins; nostril connected with mouth by a deep groove, its anterior margin with a well-developed fleshy barbel (tentacle). Teeth small, with several cusps; development ovoviviparous in some, oviparous in others. Some species (carpet sharks) live on the bottom and are ornamented with fleshy flaps along the sides of the head. Large family of many genera and species occurring mostly in western Pacific, Australasia, Indian Ocean, Red Sea. Only 1 species, the nurse shark, in Atlantic.

Family Rhincodontidae (whale shark). Distinguished from all other sharks by large, lunate tail, mouth at end of snout, 3 prominent ridges extending the length of body along the sides, back marked with round white or yellow spots and a number of white or yellow transverse stripes. Oviparous. Size said to reach over 18 m (59 ft), the largest of modern fishlike lower vertebrates. One species only (*Rhincodon typus*); open waters of all oceans, mostly in tropics, but north to 42° N latitude (near New York) and south to 33°55′ S (Table Bay, South Africa). Sluggish and inoffensive.

Family Scyliorhinidae (cat sharks, European dog shark, swell sharks). Upper Jurassic to present. Most with 2 dorsal fins (1 genus with 1); first dorsal fin situated far back on body, at least half of it behind the origin of the pelvic fins. Furrows are more or less developed at the angle of the jaws; teeth small, numerous, with several cusps. A large group of small sharks comprising many genera, occurring in temperate to tropical latitudes. The swell sharks (*Cephaloscyllium*) can inflate the belly with air or water, presumably a defense mechanism. Of little, if any, commercial value; harmless to man.

Family Pseudotriakidae (false cat sharks). Distinguished by the base of the first dorsal fin being at least as long as the caudal fin. Teeth minute, numerous. One genus, *Pseudotriakis;* 2 species, 1 on both sides of the North Atlantic, the other in the western Pacific. Size to nearly 3 m (about 10 ft). Deepwater sharks (taken down to 1,477 metres [4,850 ft]) rarely straying near shore and known only from a few specimens.

Family Triakidae (smooth dogfishes). Upper Cretaceous to present. The principal distinguishing feature is small, closely crowded teeth in series, rounded or somewhat compressed and with 3 or 4 cusps. True nictitating membrane lacking in eye. Development ovoviviparous or viviparous. Small sharks of coastal waters in tropical to temperate zones of all oceans. The family comprises at least 7 genera and numerous species. Smallest species, *Triakis barbour,* reaches only about 40 cm (16 in.); maximum size for others of family 150–175 cm (59 to 69 in.). Although sharks of this family are generally considered harmless, there is one authenticated case of a California leopard shark (*Triakis semifasciata*) attacking a man in northern California.

Family Carcharhinidae. The largest family of sharks, with 13 genera and numerous species, including the tiger shark, the great blue, whalers, and many with various local common names. Upper Cretaceous to present. Two dorsal fins, the first in front of the pelvics. All species except 1 with well-developed nictitating membrane. Teeth bladelike, with only 1 cusp, only 1 or 2 rows functional along sides of jaws. Development either ovoviviparous or viviparous. The species range in maximum size from about 1.4–5.5 m (about 4½ to 18 ft). Members of this family occur from tropical to temperate zones in all oceans. Although most species are marine, several frequent brackish water or freshwater, and some occur in lakes that connect with the sea. The *Carcharinus leucas-gangeticus* group, a collection of several closely related species or subspecies, has a bad reputation; several cases of unprovoked attacks on persons are on record in both salt water and freshwater.

Family Sphyrinidae (hammerhead sharks). Upper Cretaceous to present. The most obvious distinguishing feature is the lateral expansion of the head in a hammer or bonnet form, with the eyes at the outer edges. Teeth large, triangular, smooth edged in some species, serrate in others. Viviparous or ovoviviparous; size varies with species, the largest (*Sphyrna mokarran*) is said to reach 6 m (about 20 ft). Predacious. Marine, but occasionally straying into estuaries. Occur in tropical and temperate zones of all seas. Hammerheads have a sinister reputation of initiating unprovoked attacks, documented by authoritative cases on record.

Suborder Squaloidei (spiny dogfishes, bramble sharks, sleeper sharks, pygmy sharks). Upper Cretaceous to present. Widely distributed, found in all of the oceans from tropical to both Arctic and sub-Antarctic latitudes; from shallow to deep depths. Anal fin lacking; snout not elongated into a beak; body subcylindrical (nearly round in section); not flattened dorsoventrally; margins of pectoral fin not expanded forward past first pair of gill openings.

Family Squalidae (spiny dogfishes, sleeper sharks and several others lacking common names). Upper Cretaceous to present. Distinguished by having about as many upper teeth in anterior row as in succeeding rows. Diverse forms, habits, and sizes. Spiny dogfishes (*Squalus*) grow to about 120 cm (47¼ in.); the Greenland sleeper shark to over 6 m (about 20 ft); a pygmy shark (*Euprotomicrus*) to about 26 cm (10¼ in.). Sleeper sharks (*Somniosus*) taken for food in waters around Iceland and west Greenland, but the fish must be dried before eating; otherwise it produces a mild poison.

Family Oxynotidae (prickly dogfish). Miocene to present. Distinguished by number of functional upper teeth increasing in each row from front to rear; dermal denticles large and prominent. Taken from depths of 60–530 m (about 200 to 1,740 ft); 2 species known in eastern North Atlantic, Tasmania, and New Zealand.

Suborder Pristiophoridei

Family Pristiophoridae (saw sharks). Cretaceous to present. Anal fin lacking, snout greatly elongated, each edge studded with sharp toothlike structures; upper eyelid is free; gill slits at the side of the head, not underneath as in the sawfish. Ovoviviparous. Marine. Indo-Pacific, South Africa, Tasmania, Australia, Philippines, Korea, Japan. The order comprises 1 family, 2 genera, *Pristiophorous,* with 5 gill openings, and *Pliotrema,* with 6. Good food fish, harmless to man.

Suborder Squatinoidei

Family Squatinidae (angel sharks). Upper Jurassic to present. Marine, widely distributed in continental temperate and warm waters of Atlantic and Pacific oceans, on or close to the sea bottom. Characterized by flattened body, eyes on upper surface; anterior margin of pectoral fins far overlapping gill openings, which are partly on side of body; no anal fin. Largest up to about 2.4 m (about 8 ft). Ovoviviparous. One genus; possibly as many as 11 species.

Order Batoidei (rays, sawfishes, guitarfishes, skates, and stingrays)

Jurassic to present. Five gill openings, wholly on ventral surface; pectoral fins united with sides of head forward past the gill opening. Differ from all sharks in lacking upper free eyelid.

Suborder Pristoidei

Family Pristidae (sawfishes). Jurassic to present. Distinguished by extension of snout into long, narrow, flattened blade armed on either side with teeth but without barbels; gills on lower side of body, as in other batoids. Ovoviviparous. Size varies with species; common Atlantic sawfish to at least 5.5 m (18 ft); species in Indian and Australian waters to over 7 m (23 ft). Widely distributed in tropical and subtropical zones of all oceans; occur in estuaries and run far up large rivers into freshwater; but whether they remain resident and reproduce in freshwater lakes is not clearly established. Six species are known.

Suborder Rhinobatoidei (guitarfishes). Lower Jurassic to present. Electric organs are lacking; well-developed dorsal and caudal fins are present; base of tail is stout, not sharply marked off from rest of body. Most species are ovoviviparous, some perhaps oviparous.

Family Rhynchobatidae. Cretaceous to Recent. Distinguished by caudal fin being conspicuously bilobed and somewhat lunate; posterior edge of pectorals does not reach fore-margin of pelvics. Two genera, widely distributed in tropical and subtropical shallow waters of Indo-Pacific. Maximum size over 2 m (6½ ft).

Family Rhinobatidae. Caudal fin not bilobed; posterior edges of pectoral fins extending rearward at least as far as the origin of the pelvics. Small, rounded, closely set teeth. About 7 genera and 26 species; tropical and warm temperate shallow coastal waters of all oceans, in some localities entering freshwater and perhaps even permanently residing and breeding there. Size to about 1.8 m (about 6 ft). Harmless to bathers.

Suborder Torpedinoidei (electric rays, numbfishes, torpedoes). Eocene to present. Distinguished principally by highly developed electric organs on either side of the head and gill chambers; the outlines of these organs visible externally in most species. Pectoral fins with the head form a circular or ovate disk. Skin of most species soft and entirely scaleless. Eyes small, fuctional in most species but rudimentary or obsolete in deepwater forms. Mostly sluggish bottom dwellers in all the oceans from tropical to temperate latitudes and from the intertidal zone to depths of at least 1,100 m (3,600 ft). Three families, Torpedinidae, Narkidae, and Temeridae, distinguished by whether 1, 2, or no dorsal fins are present. Numerous genera and species. The largest electric rays of the genus *Torpedo* reach a length of about 180 cm (71 in.); the smallest, of the genus *Narke,* less than 30 cm (about 12 in.).

Suborder Rajoidei (skates). Lower Cretaceous to present. Moderately slender tail, on which the caudal fin is reduced to a membranous fold, though sometimes the caudal fin is entirely lacking; outer margins of the pelvic fin are more or less concave or notched. It is probable that all of the species are oviparous. Three families are distinguished by whether 1, 2, or no dorsal fins are present.

Family Rajidae (the great majority of skates). Two dorsal fins. Upper surface of the body disk more or less rough with spines, thornlike denticles, or both. Some species with electric organs along the sides of the tail, which, as far as known, produce very weak shocks. Six genera, widely distributed from tropical to subarctic belts of both hemispheres but with curious gaps in distribution; scarce, if present, in the Micronesian, Polynesian, and Hawaiian islands in the Pacific, in the western Atlantic between Yucatán and mid-Brazil, and in West Africa between Cape Verde and Walfish Bay. They occur from estuaries seaward, several species down to depths of over 500 m (1,640 ft). Several species inhabit deep water, at last one being found at over 2,700 m (almost 9,000 ft). They live mostly on the bottom, often partially buried.

Family Arhynchobatidae. Distinguished from other skates by having a single dorsal fin. Single genus and species, *Arynchobatis asperimus,* known only from New Zealand.

Family Anacanthobatidae. No dorsal fin; completely smooth skin; the pelvic fins so deeply notched as to form leglike structures anteriorly. Two genera, *Anacanthobatis* from Natal coast, South Africa, and *Springeria* from Gulf of Mexico.

Suborder Myliobatoidei. Upper Cretaceous to present. Distinguished by a slender tail, usually whiplike toward the tip; outer margin of the pelvic fins being straight or convex. Most with 1 or more saw-toothed, poisonous spines on upper surface of tail. Seven families are recognized. Tropical to warm temperate waters of all oceans, most abundant in shallow depths, entering brackish water and freshwater freely. One family is confined to freshwater.

Family Dasyatidae (whip-tailed rays). Lower Cretaceous to present. Caudal fin lacking; no distinct dorsal fin; tail, measured from the anus to the tip, longer than the breadth of the disk. Ovoviviparous. Tropical to warm temperate latitudes in all oceans. Generally in depths less than about 100 m (328 ft), most abundant close to shore, including tidal embayments. The largest reaches at least 2 m (6½ ft) in breadth. Five genera, 2 in tropical and subtropical rivers of South America. A peculiarity in the structure of the pelvis has been used to differentiate a separate family, Potamotrygonidae.

Family Gymnuridae (butterfly rays). Miocene to present. Distinguished by the body being more than 1.5 times as broad as long and the tail considerably shorter than the body. Saw-toothed spine on the back of the tail in some species but not all. Maximum breadth about 2 m (6½ ft). Shallow coastal waters of tidal embayments and river mouths in tropical to warm-temperature latitudes of all oceans.

Family Urolophidae (stingrays). Eocene to present. Distinguished by having well-developed tail fin supported by cartilaginous rays; tail with at least one large saw-toothed spine. Ovoviviparous. The numerous species look very much alike; the largest does not exceed about 70 cm (27½ in.) in breadth. Tropical to warm temperate coastal waters less than about 70 m (230 ft) deep in western Atlantic and both sides of the Pacific from Japan to Tasmania, including the East Indies; they are unreported from eastern Atlantic or the Indian or African coasts of the Indian Ocean.

Family Myliobatidae (eagle rays). Upper Cretaceous to present. Distinguished from other myliobatoids by the forepart of the head projecting conspicuously beyond the rest of the body; eyes and spiracles on the sides of the head; tail as long as the disk or much longer and in most species bears a serrate venomous spine. Ovoviviparous. Some attain a width of about 2.5 m (about 8 ft). Cosmopolitan, occurring in continental waters and around islands and island groups from tropical to temperate latitudes; 4 genera.

Family Rhinopteridae (cow-nosed rays). Upper Cretaceous to present. Similar to eagle rays except that the projecting head is deeply incised at the midline, forming two distinct lobes. Ovoviviparous. Maximum breadth about 2 m (about 6½ ft). Coastal waters of tropical and warm temperate latitudes of all oceans.

Family Mobulidae (devil rays, or mantas). Pliocene to present. Continental waters and around offshore island groups of tropical to warm temperate belts of all oceans. Distinguished by a pair of armlike structures (cephalic fins) projecting forward, one on each side of the head. Tail whiplike; with or without a serrate edged spine. Teeth minute, arranged in many rows. Maximum size (breadth) of smallest species about 60 cm (about 24 in.); largest species at least 7 m (23 ft).

Subclass Holocephali (chimaeras, ghost sharks)

Upper Devonian to present. Cartilaginous skeleton, 4 pairs of gills, covered on each side of the body by an opercular fold of skin leading to a single external gill opening. First dorsal fin and spine erectile. Skin with small denticles along midline of back in some species and on tentacula and claspers of males. Teeth united to form grinding plates. Claspers of males are supplemented by an erectile organ, called tentaculum, in front of the pelvic fins, and all except one genus (*Harriotta*) have another club-shaped tentaculum on the forehead. Oviparous, laying elliptical, spindle-shaped, or tadpole-shaped eggs enclosed in brown horny capsules, remarkably large in proportion to the size of the parent. In breathing, chimaeroids take in water chiefly through the nostrils and thence through grooves leading to the mouth, which is generally kept closed. Variously distributed in temperate and boreal zones of all oceans, in coastal waters, and river estuaries and seaward down to over 2,500 m (8,200 ft).

Order Chimaerae

Family Chimaeridae (ghost sharks, ratfishes, chimaeras). Lower Jurassic to present. Rounded short or conical snout. Claspers of males bifid or trifid. Size to about 1.5 m (about 5 ft). Warm temperate and boreal latitudes of all oceans. Two genera, each with several species.

Family Callorhinchidae (elephant fish). Hoe-shaped proboscis. One genus (*Callorhinchus*) with a few species, which may eventually prove to be identical. Size to about 1.3 m (4 ft 3 in.). Restricted to cool temperate and boreal latitudes of Southern Hemisphere, generally taken in rather shallow water, sometimes entering estuaries and rivers.

Family Rhinochimaeridae (long-nosed chimaeras). Snout projecting into a long, straight point. Lateral line an open groove. Size to about 1.3 m (4 ft 3 in.). Probably cosmopolitan in middle latitudes of both hemispheres, taken in depths of 685–2,000 m (2,250 to 6,560 ft).

Critical appraisal. Many of the elasmobranchs are difficult subjects for taxonomic study. Differences between species are often subtle and hard to measure. Lacking skeletal support such as that possessed by the bony fishes, captured sharks collapse along the soft undersides of the body when taken out of the water, thus reducing the accuracy of measurements. A satisfactory taxonomic study of any species requires adequate samples over a full range of sizes, representing the full geographical distribution of the species. The sampling allow for rather large variations in body proportions between individuals of like size and different size groups and between populations inhabiting different regions of the total distribution. Hence, the identity of many species remains unsettled. The number of living species of sharks, now estimated at 200 to 250, tends to diminish as ichthyologists in different parts of the world accumulate and exchange careful anatomical measurements of fresh specimens, discovering that fishes from widely separated areas, formerly thought to be distinct, are actually of the same species.

The rays, except the larger ones, are somewhat easier to work with. About 300 to 340 species have been described. Here again, however, the number tends to diminish as comparative studies in different parts of the world show many of them to be cosmopolitan.

The classification of chondrichthyed fishes is a somewhat controversial subject. An authoritative opinion as to how sharks, rays, and chimaeras should be grouped can be reached only from a comprehensive critical review of all available pertinent living and fossil material. Students continuously add to the accumulation of field measurements and museum specimens, and so such a classification needs to be revised from time to time. Because this revision involves a vast amount of work, it is not undertaken often. (L.A.Wa.)

The fleshy-finned fishes (Sarcopterygii)

COELACANTHS (CROSSOPTERYGII)

The Crossopterygii constitutes a largely extinct subclass of primitive bony fishes that appeared at the beginning of the Devonian Period (395,000,000 years ago) but are now represented only by the coelacanth (*Latimeria chalumnae*).

General features. One major trait of the subclass is the division of the skull into an anterior, or ethmosphenoidal, unit and a posterior, or oto-occipital, unit, similar to the two cartilaginous prototypes found in the embryonic cranium. A strong joint unites the two regions at each side. The base of the skull and the vertebral column, which are incompletely ossified, allow the persistence, to various degrees, of the initial skeletal axis, or notochord. The subclass comprises three orders: Rhipidistia, Actinistia, and Struniiformes. Some authorities consider the Crossopterygii to be an order and what are treated here as orders to be suborders. After being widely distributed around the world in the Mesozoic Era, which began about 225,000,000 years ago, the crossopterygians underwent a rapid decline and then almost became extinct after the Triassic Period (190,000,000 years ago).

The Rhipidistia, predatory fishes of the Mesozoic, were ancestral to the terrestrial vertebrates, lived in freshwater, and probably had two respiratory apparatuses, a branchial (gill) system for aquatic respiration and a pulmonary (lung) system for air breathing. To facilitate air breathing the nasal cavities were provided with posterior nares (nostrils) homologous with the primary choanae (internal openings to the pharynx) of more advanced vertebrates. The skeletal structure of the paired fins clearly shows the ability for locomotion both on solid ground and in the water. The rhipidistians are thus credited, in the history of vertebrate evolution, with having made the great transition in anatomy and physiology involved in the emergence from water and resulting in the evolution of the amphibians. A Swedish paleontologist, E. Jarvik, has suggested that the rhipidistian Osteolepiformes gave rise to the Stegocephalia (the extinct ancestors of reptiles, birds, and mammals) and the Anura (frogs) and that the suborder Porolepiformes gave rise to the Urodela (salamanders).

Importance in the evolution of land animals

The Actinistia, especially the family Coelacanthidae, un-

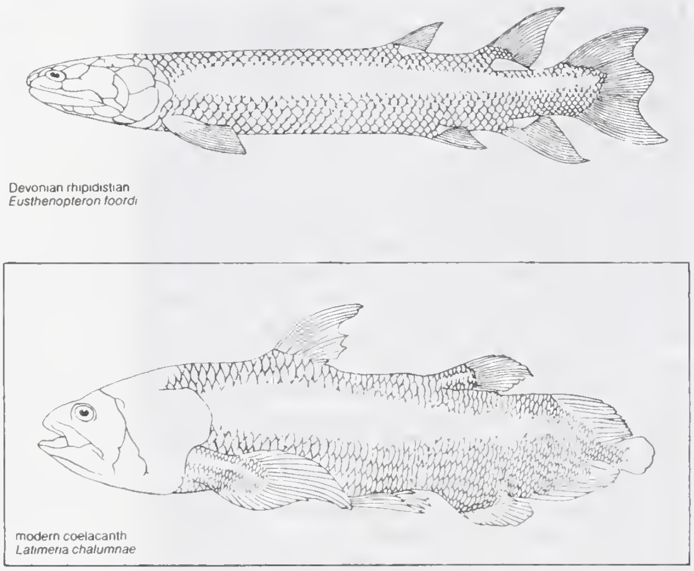

Figure 11: Representative crossopterygians.
Drawing by T. Kovacs based on (Top) *De tidiga fossila Ryggradsdjuren* (1959)

like the Rhipidistia, have exhibited exceptional evolutionary stability. The same fossil deposits contain both marine and freshwater types, both already specialized during the Devonian. They were thought to have disappeared 50,000,000 to 70,000,000 years ago, but in 1938 a live specimen was taken in the Indian Ocean. South African ichthyologist J.L.B. Smith identified it as a member of the Coelacanthidae and named it *Latimeria chalumnae,* the generic name in honour of Miss Courtenay Latimer, an associate who first brought the strange fish to his notice, the species name recalling its capture near the mouth of the Chalumna River. Between 1952 and 1970, more than 60 specimens of *Latimeria* were caught on the volcanic slopes of the Comoro Islands, at depths of 200 to 300 metres (650 to 1,000 feet).

Form and function. *Latimeria* has made it possible to reconstruct, with a high probability of accuracy, the anatomy of the coelacanths in general, in particular that of the perishable organs. Among the most striking characteristics are those of the head. The brain exhibits a relatively simple and harmonious structure, has an extremely small volume by comparison with the cranial capacity, and shows considerable displacement of the forebrain relative to the floor of the skull. The snout contains a special sensory organ, the rostral organ. At the intracranial articulation are attached some fibrous connective tissues as well as a pair of powerful longitudinal muscles, the subcranial muscles. This pair of muscles encloses the imposing notochord (a slender skeletal structure), the morphology of which must have been largely the same throughout the crossopterygian group. The heart of the *Latimeria,* which is very primitive, exhibits almost perfect bilateral symmetry (mirror-image form). It lies within a substantial pericardial cavity that retains the primitive continuity with the peritoneal (abdominal) cavity. There is a series of small valves near the exit from the heart, and several small contractile organs attached to the branchial arteries apparently fulfill the necessary function of assisting the propulsion of blood. On the whole, an embryonic condition co-exists with specialized arrangements.

An enormous cylinder of adipose (fat) tissue, aligned with a short median diverticulum (a blind pouch) of the ventral wall of the esophagus, lies above the abdominal organs. It apparently is a result of the degeneration of a lung apparatus. The extraordinary size of this cylinder is related to a displacement of the kidneys that undoubtedly occurs in the course of development, these organs occupying an unusual ventral position, posterior to the anus. Segments of the sympathetic nervous system are carried along in this movement.

Fins

The body is covered with large rough scales. The powerful tail fin has three lobes, lying in the median plane. The posterior end of the notochord extends into the middle lobe, which is by far the smallest. Two pairs of fins, the pectoral and the pelvic, are attached to their respective girdles. The base of each fin consists of a fleshy stalk supported by several successive segments of bone or cartilage that are not homologous with the similar parts of the Rhipidistia. Median fins similarly formed grow from the posterior part of the body, the posterior dorsal (above) and anal (below) fins. Finally, there is an anterior dorsal fin which, in contrast to the foregoing, is of ray-finned (actinopterygial) type—*i.e.,* lacking the fleshy, supportive stalk.

The Struniiformes, discovered only recently, lived in the Devonian. Their bony remains indicate considerable differences from both the Rhipidistia and the Actinistia. The fossil remains indicate, however, that they possessed the major characteristic of the subclass, the division of the cranium into an anterior and a posterior part.

(J.D.A./Ja.M.)

LUNGFISHES (DIPNOI)

The Dipnoi comprise an order of fishes that first appeared in the Lower Devonian Period (about 370,000,000–395,000,000 years ago) and that today is represented by only six species. Some authorities recognize only three extant species. Known as lungfishes, the extant species occur in Africa, South America, and Australia. They are especially interesting because of their characteristic body forms, their generally large size, their erratic distribution over the tropical regions of the earth, and their peculiar mode of life.

General features. *Economic importance.* The economic importance of the lungfishes is slight. Only in certain parts of Africa, because of their abundance and size, are they of any value to man as food. They are obtained from the mud of dried river bottoms. The South American lungfish, which is obtained in the same manner, is eaten locally.

Size range and distribution. Most species grow to substantial size. The Australian lungfish, *Neoceratodus forsteri,* attains weights of up to 10 kilograms (about 22 pounds) and a length of 1.25 metres (about 50 inches). Of the African lungfishes, the yellow marbled Ethiopian species, *Protopterus aethiopicus,* is the largest, growing to a length of two metres (about 80 inches). The South American species, *Lepidosiren paradoxa,* reaches a length of 1.25 metres (about 50 inches).

The distribution of the Dipnoi strikingly parallels that of the unrelated osteoglossomorph fishes, another freshwater group. The Australian lungfish occurs in a very small region of Australia: in the marshes of Queensland, along Burnett River and St. Mary's River. Four species (*Protopterus*) occur in Africa, where they are chiefly concentrated in the equatorial belt, but occur as far north as Senegal and as far south as Mozambique. Within their areas of distribution, the African protopterids are abundant along the riverbanks, in submerged areas with plant cover, and in lakes. *Lepidosiren paradoxa,* the South American lungfish, is widely distributed in that continent. It is especially numerous and often associated with the "eel" *Synbranchus marmoratus* in the shallow and muddy watercourses of the Chaco River in Paraguay and in neighbouring areas.

Drawing by J. Helmer from (*Lepidosiren, Protopterus*) J.R. Norman *A History of Fishes* (1947), Hill & Wang Publishers, (*Dipterus*) A.S. Romer *The Vertebrate Story,* Copyright 1933, 1939, 1941, 1959 by the University of Chicago

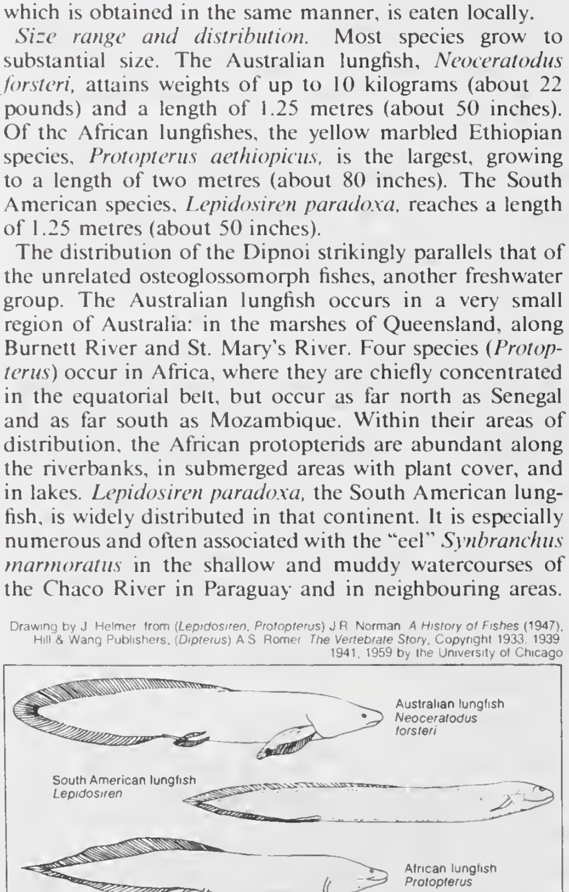

Figure 12: Living and fossil forms of Dipnoi fishes.

Natural history. *Reproduction and life cycle.* The African lungfishes spawn in the last half of winter, the onset of the rainy season. *Protopterus* species build a nest in the form of a pit on the bottom of a watercourse. The egg is about 3.5 to four millimetres (just over 1/8 inch) in diameter, and the tiny larvae emerge a week after the eggs are laid. The larvae have long, bright red, tuftlike or fanlike external gills, which they use for breathing until the lungs are fully developed. The young at first remain in the nest under the protection of the male.

The South American lungfishes dig a nest in the bottom in the form of a vertical passage, which frequently turns horizontally at the bottom. The male remains in the nest and guards the brood. During the spawning season, the pelvic fins of the male develop numerous tuft-shaped growths filled with small blood vessels (capillaries). These growths are believed to release oxygen from the blood, thereby oxygenating the water around the young.

The Australian lungfish lays gelatinous eggs among waterplants; the larvae, which have no external gills, breathe through internal gills.

Behaviour and ecology. Lungfishes are voracious, eating a variety of aquatic animals, including members of their own species. In captivity, African lungfishes eat earthworms, pieces of meat, tadpoles, small frogs, and small fish. The Ethiopian lungfish has at the front of the upper jaw two rather rounded teeth with a hard transverse (from side to side) bridge. The lower jaw has a number of crushing teeth. The prey is sucked in, crushed, and thoroughly chewed; such a manner of eating is rare among fishes.

Fins as sense organs

Form and function. *General features.* The slim, eel-like African protopterids and the even slimmer South American *Lepidosiren paradoxa* have long, stringy, very mobile pectoral and pelvic fins that are in a constant state of agitation—touching and sensing surroundings. The tips of these fins have a highly developed sense of touch, which, together with the fish's well-developed sensitivity to pressure and turbulence and its good sense of smell and taste, largely make up for the weakness of the eyes. The fish are almost blind with respect to the perception of form and movement. Pressure and turbulence are sensed by means of sensory structures called lateral lines. At the anterior, or head, end, the lateral lines are modified into a pattern of intricately interlaced bright lines, which are a series of tiny bud-shaped terminal organs. The highly individual patterns are used in distinguishing species.

The Australian lungfish has an entirely different appearance. It is more compactly built and has large, overlapping scales. The pectoral and pelvic fins are much broader. The African and South American lungfishes have paired lung sacs; in the Australian species the left lung sac atrophies.

Adaptations for breathing. There are a number of fishes that, in addition to or in place of gill breathing, have developed special organs through which they can breathe atmospheric air at the water surface. This occurs almost exclusively in freshwater fishes. In lungfishes these organs are, both in function and in structure, primitive lungs like those of amphibians. The name lungfish is thus well applied: these fishes have sac-shaped, pneumatic organs that lie along the alimentary tract. The inner surfaces of these air-breathing organs are covered with a great number of honeycomb-like cavities covered with fine blood vessels. As in terrestrial higher vertebrates, gas exchange takes place in the tiny air vesicles.

In order to breathe, the fish swims upward and positions its head so that the tip of the snout barely touches the water surface. The mouth is then opened wide, and the fish sucks in air from just above the water—a process often accompanied by a characteristic sound. The Australian lungfish reportedly breathes air through the nasal openings, the mouth remaining closed. In contrast to the higher bony fishes, lungfishes have a particular opening (choana) that connects the nasal cavity with the mouth.

In the Australian lungfish, gill breathing predominates at least some of the time—namely, in times of normal water level when the water is well oxygenated. At such times the fish rises less often to the surface to breathe atmospheric air. When the water level goes down, which usually occurs in August or September, the fish is often found in isolated waterholes in which the oxygen content is greatly reduced. Other fishes in such pools often die from lack of oxygen, but the lungfish survives, having changed over to the breathing of atmospheric air. During such a dry period the Australian lungfish surfaces about every 40 to 50 minutes for air. African lungfishes surface for air about every 30 minutes or, in some cases, at longer intervals.

The "dry sleep"

Physiology and biochemistry. African lungfishes bore into the bottom of a riverbed or lake bed for their "dry sleep." After burying themselves they become encased in a sheath that gradually hardens. Here they spend the dry season, during which the waterline becomes lower and the riverbed or lake bed finally dries out. The African lungfish generally digs in and encysts in this manner, even if there is sufficient time to swim to deeper waters. African lungfishes also burrow into mud and ensheath themselves under experimental conditions. They have been kept alive in such an induced state for more than two years.

The South American lungfish also bores into the mud in times of water shortage, but it forms no protective sheath. The Australian lungfish never buries itself in this manner.

Studies have shown that the "dry sleep" of the African lungfish is induced by a substance that inhibits the fish's normal metabolism.

Extracts from the brains of such sleeping fish injected into rats have caused them to become lethargic; in addition, the body temperature of the rats falls 5° C, and the metabolic rate falls 33 percent. The day after receiving such injections, the rats stop eating. It is believed that the substance responsible for this effect is a protein-like substance.

Evolution. The oldest Dipnoi, from the Lower Devonian Period, had skull and dental features that are characteristically dipnoid but also had many similarities to the crossopterygians (*e.g.*, coelacanth). The Dipnoi was abundant until Triassic times (190,000,000–225,000,000 years ago), after which their numbers decreased.

Dipterus, one of the oldest lungfish, had leaflike pectoral and pelvic fins similar to those of the modern Australian lungfish, and it seems reasonable to assume that early forms also had functional lungs comparable with those of species living today. Hardened sections of clay, cylindrical in shape, have been found in Pennsylvanian (about 280,000,000–325,000,000 years old) and Permian (225,000,000–280,000,000 years old) deposits. Remains of the dipnoid *Gnathorhiza,* closely allied to the extant African and South American species, were imbedded in the clay, strongly suggesting that they passed unfavourable conditions buried in mud.

An evolutionary line can be traced from *Dipterus* to *Neoceratodus,* the extant Australian genus. *Scaumenacia* and *Phaneropleuron,* common forms of the Upper Devonian (345,000,000–370,000,000 years ago), exhibited a much-reduced first dorsal fin (the first fin forward on the back); the second dorsal fin was enlarged and had shifted further toward the tail. Lungfish of Permian times showed an apparent fusion of the fins along the back and the rest of the vertical midline into the so-called diphycercal tail (*i.e.*, tapering to a point) present in modern lungfishes. Various side branches also occurred in the evolution of the Dipnoi, none of which has survived to modern times.

Classification. The annotated classification given below primarily relates to living forms; for a classification including the extinct forms see the critical appraisal below.

Distinguishing taxonomic features. The separation of Dipnoi as a discrete group is based largely on the structure and arrangement of the skull bones and the teeth. The suborders, of which there are two, are mutually distinguishable mainly by the number of lungs (one or two).

Annotated classification.

SUBCLASS DIPNOI

Lower Devonian (370,000,000–395,000,000 years ago) to Recent. Cranium not divided into movable parts; teeth in upper jaw reduced and lost in later members; some teeth fused into plates for eating shellfish. A single order.

Order Sirenoidei

Suborder Monopneuma

One functional lung.

Family Ceratidae. Pectoral and pelvic fins reduced but not tentacle-like; scales large; grows to about 1.25 m (about 50 in.); 1 living species: *Neoceratodus forsteri* (Australian lungfish).

Suborder Dipneuma
Two functional lungs.

Family Lepidosirenidae. Body eel-like in form; scales small, pectoral and pelvic fins modified into slender tentacle-like structures; passes dry periods in mud of dried river and lake bottoms; grows to about 2 m (about 80 in.); 2 living genera: *Lepidosiren* of South America (1 species: *L. paradoxa*) and *Protopterus* of Africa (4 species).

Critical appraisal. Some writers assign Dipnoi to the ordinal level, subsuming several families, mostly extinct, within that order.

The following alternate classification is according to A.S. Romer (1966), an American vertebrate paleontologist (extinct families represented only by fossils are indicated by a dagger [†]):

ORDER DIPNOI

†Family Dipnorhynchidae
Lower to Middle Devonian; Europe, Australia, North America.

†Family Dipteridae
Devonian; Europe, Greenland, North America, northern Asia, Australia.

†Family Ctenodontidae
Carboniferous (280,000,000–345,000,000 years ago); Europe, North America, Australia.

†Family Phaneropleuridae
Upper Devonian; North America, Greenland, Europe.

†Family Sagenodontidae
Mississippian to Lower Permian (250,000,000–280,000,000 years ago); North America, Europe.

†Family Uronemidae
Mississippian; Europe, North America (?).

†Family Conchopomidae
Pennsylvanian (280,000,000–325,000,000 years ago) to Lower Permian (250,000,000–280,000,000 years ago); North America, Europe.

Family Ceratodontidae
Lower Triassic (210,000,000–225,000,000 years ago) to Recent; one surviving species, *Neoceratodus forsteri.*

Family Lepidosirenidae
Pennsylvanian to Recent; 2 living genera, *Lepidosiren* and *Protopterus.* (K.H.L.)

THE HIGHER FISHES (ACTINOPTERYGII)

The early ray-finned fishes

STURGEONS, PADDLEFISHES, BICHIRS (CHONDROSTEI)

The Chondrostei comprise one of the three major subdivisions (subclasses, or infraclasses) of the class Actinopterygii, the higher, bony, ray-finned fishes. Fossilized chondrosteans first appear in rocks of the Middle Devonian Period (about 375,000,000 years ago), and some members of this subclass have persisted to the present time. The only living representatives are the sturgeons and paddlefishes; the living bichirs (polypterids and the closely related reedfish) of Africa are also considered to be chondrosteans by some ichthyologists.

Decline of the chondrosteans

The chondrosteans were most numerous and diversified during the last part of the Paleozoic Era (ending 225,000,000 years ago) and the beginning of the Mesozoic Era (beginning 225,000,000 years ago). With the rise of the holosteans and teleosts (the other two major subdivisions of the Actinopterygii) during the Mesozoic, the chondrosteans declined, until by the end of the Cretaceous Period (65,000,000 years ago) they had been reduced to a few genera.

The few living chondrosteans are highly specialized and aberrant forms. Their evolutionary history has not been clearly documented. Except for the sturgeon, which is a food fish for man and the source of caviar, they have no economic importance. A study of the living sturgeons, paddlefishes, and bichirs, however, provides some understanding of extinct forms.

General features. The chondrosteans are difficult to characterize as a group, but certain features are common to most of them. Generally the bony adult neurocranium, or braincase, is composed of two divisions, a larger ethmo-otic and a smaller occipital section. In the paddlefishes and sturgeons the braincase is mostly cartilaginous, with a few isolated areas of bone.

Drawing by J Helmer based on D.S Jordan, *A Guide to the Study of Fishes*

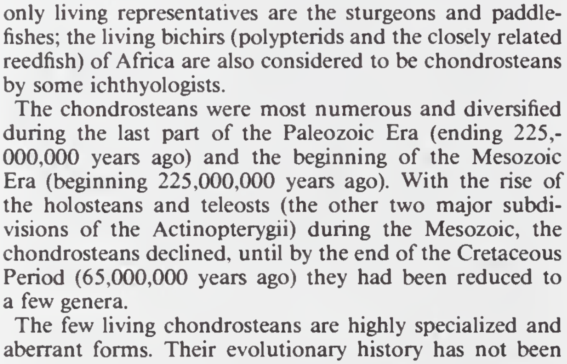

Figure 13: Body plans of modern chondrostean fishes.

Distribution and size range

The most numerous and widespread Paleozoic chondrostean fishes belong to the order Palaeonisciformes. The earliest known chondrosteans (Cheirolepidae and Stegotrachelidae), from the Middle Devonian of Europe, belong to this group. The palaeonisciforms inhabited a variety of freshwater and marine habitats and are known from all the continents with the exception of Antarctica. They reached their period of greatest number and diversity during the Carboniferous Period (280,000,000 to 345,000,000 years ago). Although the palaeonisciforms persisted with little modification into the Cretaceous, they began to show a marked decrease in numbers in the Triassic Period (190,000,000 to 225,000,000 years ago) and, by the end of the Cretaceous, had completely died out.

Modern sturgeons occur only in the waters of the Northern Hemisphere. The common sturgeon (*Acipenser sturio*) is found on the European coast from Norway to the Mediterranean Sea. A closely related form, probably of the same species, is found along the east coast of North America from the St. Lawrence River to the Gulf of Mexico. *A. gueldenstaedti* occurs in western Russia east to Lake Baikal. A smaller species, the sterlet (*A. ruthenus*), inhabits the Black and Caspian seas. *A. stellatus* occurs in rivers leading to the Black Sea, the Sea of Azov, and the Caspian Sea. The lake sturgeon of North America (*A. fulvescens*) occurs in the Mississippi valley, the Great Lakes, and northward into Canada. The white, Oregon, or Sacramento sturgeon (*A. transmontanus*) inhabits the waters of the Pacific Coast of North America from California to Alaska.

Bichirs (*Polypterus*) and the closely related reedfish (*Calamoichthys calabaricus*) occur in fresh waters of Central Africa. The Mississippi paddlefish (*Polyodon spathula*), also known as the spoonbill sturgeon, is found in the Mississippi basin; the Chinese paddlefish (*Psephurus gladius*), also called the swordbill sturgeon, occurs in the Yangtze River of China.

The length of some palaeonisciforms may have been as great as one metre (slightly more than three feet). The so-called subholosteans—a collective term for a heterogeneous group of chondrostean orders, from Perleidiformes through Parasemionotiformes (see below *Annotated classification*) probably grew to no more than 30 centimetres (about one foot) or so. Most modern sturgeons reach a length of little more than two metres (seven feet), but the hausen, or beluga (*Huso huso*), has been reported to reach 8.5 metres (28 feet). The Mississippi paddlefish grows to about 1.8 metres (about six feet), but the Chinese paddlefish sometimes reaches 6.3 metres (about 21 feet) in length. The largest species of bichir grows to about 70

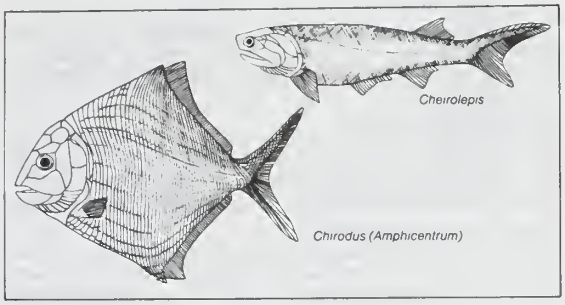

Figure 14: Examples of two chondrosteans of the order Palaeonisciformes.

centimetres (28 inches); the reedfish reaches a length of 90 centimetres (35 inches).

Natural history. *Reproduction and life cycle.* Marine sturgeons ascend rivers in spring or summer to deposit their spawn. They are abundant in the rivers leading to the Black and Caspian seas and to the Sea of Azov during the two weeks of the upstream migration. Early in summer the fish migrate into the rivers or toward the shores of freshwater lakes in large shoals for breeding purposes. The eggs are small and numerous, and the growth of the young is rapid. After the sturgeon attains maturity, growth continues at a slow rate for several years. Some attain great age: observations made in Russia indicate that the hausen may attain an age of 200 to 300 years.

Bichirs initiate courtship by leaping from the water. Little is known of their spawning habits. Young fish have external branching gills and are newtlike in appearance. Paddlefishes breed when seven or eight years old and spawn during spring floods. The larvae hatch in about two weeks and feed on their large yolk sac. The paddle, a long, broad extension of the snout, is absent at birth but begins to appear after two or three weeks.

Feeding

Ecology. Sturgeons occur in both salt water and fresh water. Ground feeders, they spend much time foraging, dragging their tactile, whiskerlike barbels over the bottom in search of small invertebrates and fishes. Paddlefishes feed by straining plankton (mostly tiny, drifting aquatic organisms) through their gill system and have been described as living plankton nets. Bichirs and reedfish mainly inhabit the edges of streams and floodplains. They remain concealed by day and forage at night for worms, insect larvae, crustaceans, and small fishes.

Form and function. *Extinct forms.* Most palaeonisciforms had fusiform (*i.e.,* tapered at both ends) bodies with blunt snouts, eyes situated far forward, pelvic fins located at about the middle of the body, dorsal (*i.e.,* back) and anal (on the lower side) fins nearly opposite one another on the posterior part of the body, and heterocercal (*i.e.,* with the top lobe longer than the lower lobe) caudal fins. With few exceptions, their bodies were covered with rhomboidal (diamond-shaped) scales, with or without a dentine layer. The scales articulated with one another by a peg-and-socket joint; in some groups, the scales tended to become thin and cycloidal, or rounded, as in the coccolepids. The rays of the unpaired fins were usually more numerous than their basal supports, and all the fins were usually bordered by scales that were generally larger and stronger than other scales (fulcral scales). A few families, such as the Late Paleozoic platysomids and amphicentrids, evolved deep, compressed bodies with elongated anal and dorsal fins.

In all palaeonisciforms, the upper jaw was tied to the cheekbones, which completely covered the area between the eyes and the gill covers. The jaw suspension may have had an oblique orientation (associated with a wide mouth gape) or a nearly vertical orientation (associated with a relatively smaller gape). The teeth either were rather well-developed or were sometimes practically absent. If present, they were generally styliform, or needlelike, in both the upper and lower jaws, and the musculature closing the mouth was rather straplike.

There is reason to believe that the biting mechanism in palaeonisciforms was less powerful than that of the holosteans. The arrangement of the fins and the structure of the tail suggest that manoeuvrability in swimming was not as great as in either the holosteans or the teleosts. Members of the Late Paleozoic order Tarrasiiformes had an elongated body and a diphycercal caudal fin that was continuous with the dorsal and anal fins. Haplolepiforms, also of the Late Paleozoic, had robust paired and unpaired fins and a relatively small number of unbranched fin rays. Like the palaeonisciforms, the subholosteans ranged from fusiform to deep-bodied.

In some subholosteans, the upper jaw was freed from the cheek elements and articulated with the skull only in the snout region. The palate and the cheek were also modified in such a way that the adductor, or closing, musculature of the lower jaw could enlarge to provide greater force in seizing prey. In connection with this, the upper border of the mandible developed an elevation (coronoid process) on its posterior part, and the attachment of part of the jaw musculature to this elevation increased the efficiency of the feeding mechanism. In the dorsal and anal fins, the number of fin rays tended to equal the number of basal supports, and the caudal fin became hemiheterocercal (*i.e.,* apparently symmetrical, but with the vertebral column turned upward and extending into the upper lobe).

Specializations for bottom feeding

Extant forms. The amount of bone in the sturgeon skeleton is less than that in the ancient forms. The modern sturgeon has bony plates on the head and five rows of bony shields along the body: one along the back, one on each side above the pectoral fins, and one on each side near the belly. The tail fin is heterocercal. The mouth is subterminal (*i.e.,* behind and below the snout tip), and this and other specializations are clearly related to bottom feeding. The mouth is toothless and is preceded by four fleshy barbels; the protractile lips have taste buds surrounding them. The form of the snout becomes more blunt and abbreviated with age.

The relationship of the paddlefishes to the sturgeons is not fully understood. The skeleton of the paddlefish, like that of the sturgeon, has lost much of its ossification. The body is fusiform, the fins well-developed, and the tail heterocercal. The elongated, paddle-shaped snout, which is composed entirely of cartilage, is one-third to one-half the total body length. The skin is smooth, except for a few scattered vestigial scales. The mouth is subterminal, and the jaw structure, particularly that of the adductor muscles, is suggestive of the palaeonisciform condition.

The bichir is rather elongated in form, the reedfish eellike; both have hard, diamond-shaped scales. The dorsal fin consists of a few to several separate finlets. The upper body is brown, grayish, or greenish, the lower side often white or yellowish.

Evolution. The long history of the chondrosteans, which extends over a period of 375,000,000 years, is marked by several important evolutionary events. The first is related to the appearance of the earliest ray-finned fishes, the palaeonisciforms. These fishes possess essentially the same feeding mechanism design and the same pattern, including a fully heterocercal tail, as later forms. The Late Paleozoic Tarrasiiformes and Haplolepiformes are obviously descended from the palaeonisciforms, but they are divergent enough to be regarded as separate orders.

The main groups of holosteans and halecostomes (which gave rise to the teleosts) apparently arose from subholostean-like ancestors during the Permian and Triassic periods. The heterogeneous subholosteans show modifications in the feeding mechanism and in the body that foreshadow the holosteans and halecostomes. Fishes referred to this unnatural group were characteristic of the Triassic Period, although a few families continued into the Jurassic (136,000,000 to 190,000,000 years ago). In general, the subholosteans can be said to show a diversity in the structure of the skeleton that was never attained by the more primitive palaeonisciforms. This diversity suggests the kind of evolutionary "experiments" that must have occurred during the rise of the various families of more advanced actinopterygians.

The origin of the order Acipenseriformes (which includes the sturgeon) is not known, although they were clearly derived from some palaeonisciform groups. Fossils that are without doubt related to the sturgeons and paddlefishes are no older than the Upper Cretaceous (about 65,000,000 to 100,000,000 years ago). Earlier, the history of this order is poorly documented and confused. Both the sturgeons and the paddlefishes became specialized early in their history and have shown only minor diversification since then.

The Polypteriformes, which include the living bichirs (*Polypterus*) and reedfish (*Calamoichthys*) of Africa, show a confusing array of palaeonisciform, holostean, and specialized characters. Some skull and scale features indicate derivation from palaeonisciform ancestors. The palate and jaws, on the other hand, suggest attainment of a nearly holostean-like pattern. However, the specialized fins, including the diphycercal tail, indicate that the polypteriforms have had a long, independent history. Fossil occurrences, which may extend back to the Early Tertiary Period (beginning 65,000,000 years ago), offer no clues to their affinity.

Classification. *Distinguishing taxonomic features.* The approximately 37 families of the Chondrostei are separated from one another, for the most part, on the basis of differences in dermal bone pattern, body shape, and fin form and position.

Two orders, Tarrasiiformes and Haplolepiformes, are quite palaeonisciform-like in many ways but diverge in other ways that clearly set them apart as separate categories.

An advanced group of some 12 orders of unrelated chondrosteans is popularly referred to as subholosteans. The different subholostean families possess various combinations of palaeonisciform and holostean characters, and they show a diversity in the structure of the skeleton that was never attained in the earlier palaeonisciforms.

Annotated classification. Groups marked with a dagger [†] are extinct and known only from fossils.

SUBCLASS (or Infraclass) CHONDROSTEI
A group that has undergone various evolutionary diversifications. The orders of the Chondrostei are specialized for certain habitats and ways of life, and many show trends toward the holostean–halecostome level of organization, especially in median fin structure and development of a hemiheterocercal tail.

†Order Palaeonisciformes
Lower Devonian to Middle Cretaceous. Mostly fusiform fishes with heterocercal tail; maxillary bone fixed; more fin rays than basal elements in the median fins; 37 families of wide distribution, early members freshwater, later marine.

†Order Tarrasiiformes
Carboniferous (about 280,000,000 to 345,000,000 years ago). Palaeoniscid-like, but with elongated body, a diphycercal tail, and dorsal and anal fins continuous with it. One family, Tarrasiidae; Scotland and Illinois.

†Order Haplolepiformes
Upper Carboniferous. Pecuiar fishes with stout, unbranched fin rays; large gular (*i.e.*, in the throat region) plates; small opercular (*i.e.*, gill cover) apparatus. One family, Europe and North America.

†Order Perleidiformes
Lower to Upper Triassic. With ganoid (*i.e.*, bony, diamond-shaped, and not overlapping) scales; fin rays equal number of basal supports rather than exceed them; tail hemiheterocercal. Three families; worldwide.

†Order Redfieldiiformes
Lower and Middle Triassic. Like Perleidiformes, but fin rays more numerous than basal elements in dorsal and anal fins. One family, Redfieldiidae, in freshwaters of South Africa, Australia, and North America.

†Order Dorypteriformes
Upper Permian (225,000,000 to 250,000,000 years ago). Deep-bodied, with very modified skull; scales confined to anterior part of trunk. One family, Dorypteridae; Europe, China.

†Order Bobasatraniiformes
Lower Triassic. Body deep, laterally compressed; fin rays slightly more numerous than basal supports; crushing dentition; pelvic fins absent. One family, Bobasatraniidae; marine; widely distributed.

†Order Pholidopleuriformes
Lower to Upper Triassic. Some relatively long and slender; dorsal and anal fins far back on body, origin of anal fin anterior to dorsal fin; fin rays more numerous than basal elements; tail hemiheterocercal; jaw support almost vertical or moderately oblique. One family, Pholidopleuridae; marine and freshwater; wide distribution.

†Order Peltopleuriformes
Upper Triassic. Large eyes; hemiheterocercal tail almost symmetrical externally; dentition weak. Two families, Peltopleuridae and Habroichthyidae; marine, perhaps some plankton feeding; Italy, China.

†Order Platysiagiformes
Lower Triassic to Lower Jurassic. Elongated, fusiform body; tail hemiheterocercal; rays of median fins probably equalled basal elements in number; teeth large, conical. One family, Platysiagidae; marine; probably predacious; Italy and England.

†Order Cephaloxeniformes
Middle to Upper Triassic. Body deep, fusiform; thick head bones and crushing dentition; tail hemiheterocercal. One family, Cephaloxenidae; marine, probably bottom-dwelling mollusc eaters; Italy.

†Order Luganoiiformes
Middle and Upper Triassic. Body fusiform; head somewhat flattened in the horizontal plane; some head bones fused; jaw suspension inclined forward; fin rays apparently equal to basal elements in number; tail hemiheterocercal. One family, Luganoiidae; marine; probably predacious midwater fishes; Italy.

†Order Ptycholepiformes
Middle Triassic to Upper Jurassic. Fusiform body; fin rays of median fins nearly equalling basal elements in number; jaw support almost vertical; teeth small. One family, Ptycholepididae; marine; presumably plankton feeders; Europe.

†Order Saurichthyiformes
Lower Triassic to Upper Jurassic. Elongate, slender; snout elongated; single dorsal fin far back on body, opposite anal fin; tail with nearly equal lobes; number of scale rows reduced, 1 dorsal, 1 ventral, and 1 along each side; jaw suspension almost vertical; teeth large, conical; jaws long. One family, Saurichthyidae; marine and freshwater; predacious; worldwide. Length about 7–150 cm (2¾ to 59 in.).

†Order Chondrosteiformes
Lower Triassic to Upper Jurassic. Body scales and skull bones reduced; snout moderately developed, maxillary and opercular bones reduced; jaw support somewhat inclined backward; median fins paleonisciform-like, rays more numerous than basal supports. Probably gave rise to sturgeons. One family, Chondrosteidae; marine; some were suctorial feeders like sturgeons; England.

†Order Parasemionotiformes
Lower Triassic. Near holosteans in dermal skull structure. Two families; marine; Siberia, Greenland, and Madagascar.

Order Acipenseriformes (sturgeons and paddlefishes)
Upper Cretaceous to Recent. Almost no internal ossification; platelike scales in isolated rows (Acipenseridae); snout enlarged and tactile (Polyodontidae); median fins chondrostean in having more fin rays than basal elements; tail heterocercal. Marine and freshwater, bottom suctorial feeders (sturgeons, Acipenseridae; Europe, Asia, North America) and plankton feeders (paddlefishes. Polyodontidae; China and North America). Length (sturgeons) up to 8.5 m (about 28 ft); weight to 1,400 kg (3,080 lbs.).

Order Polypteriformes (bichirs and reedfish)
Pleistocene to Recent. Typical chondrostean characters, such as ganoid scales. Dorsal fin modified into row of finlets; tail diphycercal; freshwater; Africa.

Critical appraisal. Because they are a fairly uniform group, the classification of the Chondrostei is difficult and unsettled. About 37 families are now recognized. The relationships of bichirs and the reedfish are especially controversial. Some authorities place them in a separate subclass; others conclude that they are related to the crossopterygians. (B.Sc./Ed.)

BOWFIN, GARS (HOLOSTEI)

The Holostei are one of the three major groups of rayfinned fish (Actinopterygii). Most paleontologists divide the Holostei into the Holosteans proper, which include living and extinct forms, and the Halecostomi, an extinct group.

The origin of the Holosteans and the Halecostomi is not fully understood, but it is believed that they arose from some advanced chondrostean fishes (the group that includes the sturgeon; see above). The Holostei were particularly abundant and diversified during the Mesozoic Era (65,000,000–225,000,000 years ago). Today they are represented by only two living genera, *Amia* (bowfin) and *Lepisosteus* (gar). One species of bowfin has been recognized, and about eight species of gar have been described so far.

Size range, distribution, and abundance

The gar occurs only in North America and Central America from southeastern Canada to Panama; it is not found west of the Rocky Mountains. The longnose gar (*L. osseus*) is the most widely distributed species. The gar is primarily a freshwater fish but sometimes ventures into saltwater or brackish water. The so-called alligator gar (*L. spatula*), one of the largest of freshwater fishes, is particularly abundant in the Everglades region of southern Florida, where it is caught locally as a food fish; it sometimes grows to a length of nearly three metres (10 feet) and may attain a weight of 136 kilograms (300 pounds). The names gar, garfish, and garpike are sometimes applied, especially in Europe, to the needlefishes (Belonidae), which are coastal fishes of warm seas and have very long and slender jaws. These fishes, however, are not closely related to the Holostei.

The bowfin, also known as grindle, mudfish, and dogfish, is found in sluggish waters from the Great Lakes to the Gulf of Mexico. It was once common throughout Europe but is now extinct there. Female bowfins reach a length of about 75 centimetres (30 inches) and weigh up to 3.5 kilograms (eight pounds); males are smaller. Bowfins eat all kinds of fish and invertebrates and are sometimes destructive to game-fish populations. Bowfins are seldom caught as food fish.

Drawing by J. Helmer, from (top centre) N.B. Marshall, *The Life of Fishes* (1965), Weidenfeld & Nicolson, London, (bottom) A.S. Romer, *Vertebrate Paleontology* (1966), University of Chicago Press

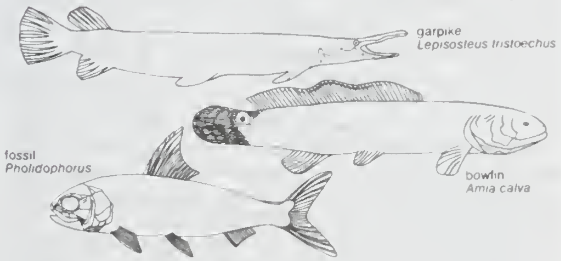

Figure 15: Living and fossil forms of Holostei.

Natural history. *Reproduction.* The bowfin spawns in weedy areas along the edges of streams and lakes. The male constructs the nest and guards the eggs as well as the newly hatched young. The young bowfin has an adhesive organ at the tip of its snout that enables it to cling to weeds. The fish grows rapidly and at the end of its first year may be as long as 23 centimetres (nine inches).

The female gar lays its large, yolk-filled eggs in shallow water in the spring. The gar hatchlings grow rapidly, feeding on minnows. The long rows of needle-sharp teeth are effective in capturing fast-swimming prey.

Ecology. Gars and bowfins are voracious predators, feeding on invertebrates and other fishes. All the amiiform fishes (the bowfin order) of former times were probably predaceous. For the most part they were a marine group; the modern bowfin, however, is confined to freshwater. Because of its highly developed air bladder, which can also function as a lung, the bowfin is able to live out of water for as long as 24 hours.

Gars are known to occasionally venture into saltwater, but apparently they do not attempt to feed there. They often float quietly at the surface of sluggish waters, breathing atmospheric air.

Form and function. *General features.* The Holostei are characterized by having the dermal bone of the upper jaw (maxilla) freed from the cheek elements and attached to the skull only in the ethmoid region or near the nasal chambers. The palate is separated from the cheek elements, and the adductor mandibulae muscle, which closes the jaws, is larger and more subdivided than it is in the chondrosteans. Primitively, the centrum (*i.e.*, the lower, heavy part of a vertebra) surrounding the notochord (a flexible rod that passes through the vertebral column) was absent, but this structure apparently developed independently in most of the holostean orders. The scales, too, were primitively rhomboidal, or diamond shaped, with a reduced or absent layer of dentine (*i.e.*, the substance of which teeth are largely made). The scales, however, became thin and cycloidal (*i.e.*, rounded and overlapping) in several groups. The fin rays of the unpaired fins are always equal in number to their basal supports, and the fins themselves may or may not be bordered at the anterior end by fulcra (*i.e.*, modified scales or spines). The caudal, or tail, fin is typically hemiheterocercal (*i.e.*, the upper lobe larger than the lower) and externally symmetrical. The braincase is always composed of separate ossifications (centres of bone formation) that resemble, in number and placement, those found in the teleosts.

The division Holosteans includes the orders Semionotiformes, Pycnodontiformes, Amiiformes, and perhaps Pachycormiformes. In these orders the preoperculum (an L-shaped bone anterior to the operculum, or gill cover) is tied to the palatal elements and provides part of the originating area for the adductor mandibulae muscle.

Extant groups. The order Seminonotiformes includes two families. The oldest known holostean, *Acentrophorus* (Upper Permian—about 225,000,000,000–250,000,000 years ago), belongs to the Semionotidae. Members of this family have small mouths and strong teeth; heavily ossified (*i.e.*, composed of true bone rather than cartilage) dermal bones; and hemiheterocercal tails. The body may be fusiform (*i.e.*, tapered at both ends), as in *Semionotus*, or flat and disk-shaped, as in *Dapedium*.

The other semionotiform family, the Lepisosteidae, includes the living gar. The characteristic snout of the gar is greatly lengthened by multiplication of the small tooth-bearing bones anterior to the eye. The premaxilla bone is situated at the anterior end of the series; the maxilla bone itself elongated seems to be reduced to a small, bony sliver at the angle of the mouth.

Body structure of living gars

The body of the gar is encased in an armour of thick, diamond-shaped, enamelled scales. The jaw ends in a beak that, in the alligator gar, is broad and relatively short; in the longnose gar the beak is long and forceps-like. The dorsal and anal fins, both located far back on the body, are without spines and have fewer than 12 rays each.

The Amiiformes, represented today by one species of bowfin, include about six families that show considerable diversity in the length of the jaw, the development of the teeth and fins, and details of the dermal skull pattern. In general, the earlier amiiforms had well-developed rhombic scales and a persistent notochord. In later forms the scales usually became thinner and cycloidal. Ossified centra developed around the notochord, either restricting it or eliminating it. The caudal fin was either forked or lobed. The amiiform body was generally fusiform, similar to that of the living bowfin.

The bowfin has a long, spineless dorsal fin with about 58 rays. This extends over most of the back to near the tail. The males have an orange- or yellow-encircled dark spot near the tail. In females either the outer circle or the entire marking is absent. Bony plates cover the head; the rest of the body has cycloid (*i.e.*, fan-shaped) scales.

Extinct groups. In some ways the Pachycormiformes superficially resemble certain living teleosts, such as mackerels and swordfishes. Their bodies are generally fusiform, with a widely forked caudal fin, a fairly wide gape, and moderately well-developed teeth. The pectoral fins may be elongated and the dorsal and anal fins somewhat enlarged.

The Pycnodontiformes, which may be related to the Semionotiformes, are unique among the holosteans in having their upper and lower dentitions modified to form an open pavement of crushing teeth. In many cases, however, the anterior teeth of the premaxilla and the dentary are incisiform and thus must have been used for grasping (as such teeth are in the living porgies and sparids). In addition to skull modifications related to feeding, the pycnodonts are characterized by deep, almost disk-shaped bodies, elongated anal and dorsal fins, and an externally symmetrical caudal fin. In a number of genera scales are absent on the posterior part of the body, a condition that apparently increased flexibility. Scales were usually present but modified on the anterior half. The body and fin form of pycnodonts suggest that they were fairly fast and powerful swimmers. The affinities of this order remain problematical, as the ossification pattern of the braincase and the caudal-fin skeleton do not closely resemble those of other Holosteans or Halecostomes.

The second major division of the subclass Holostei is the Halecostomes; all are relatively small, fusiform fishes. The group presently includes only one order, the Pholidophoriformes. Some authorities include a second order, Leptolepiformes.

Historical origin of gars and bowfins

Evolution. The gars probably arose in the Cretaceous Period (136,000,000 to 65,000,000 years ago) from some semionotid stock. They are known from freshwater Tertiary deposits in India, Africa, North America, and Europe. The bowfins also made their first appearance in Cretaceous times. Pycnodont fossils range from the Upper Triassic to the Eocene (from about 190,000,000 to 50,000,000 years ago). Pachycormiforms are known only from marine rocks of Jurassic and Cretaceous age. The pholidophorids are known from the Triassic to the Cretaceous; the other pholidophoriform families all ranged from the Jurassic to the Cretaceous.

Among the seven families presently assigned to the Pholidophoriformes, the pholidophorids probably show the closest resemblance to the early teleosts. Trends toward thinning of the scales and the loss of ganoin (an enamel-like material) on the fin rays, along with the dermal-bone pattern and the development of intermuscular bones, point toward the teleosts. The major difference between the pholidophorids and the teleosts is in the structure of the caudal-fin skeleton. In pholidophorids of the early Jurassic, the caudal fin was still structurally heterocercal, with a fairly stiff axial lobe. Modification toward the teleost condition involved changes that brought about equal flexibility of the upper and lower lobes. The other six families currently assigned to the order Pholidophoriformes are specialized in various ways, but none can be regarded as involved in the ancestry of the teleosts.

Classification. Groups marked with a dagger (†) are extinct and known only from fossils.

Distinguishing taxonomic features. The principal features on which classification of the Holostei is based include general body shape, scale structure, and the number and placement of head bones.

Annotated classification.

SUBCLASS HOLOSTEI

Tail hemiheterocercal; maxilla free of preopercle; rays of median fins approximately equal in number to basal elements; trend toward thinning of scales and loss of ganoid (enamel) layer.

Division Holosteans

Preopercle intimately bound to and supporting the posterior border of the palate.

Order Amiiformes (bowfin and fossil relatives)

Lower Triassic (about 210,000,000–225,000,000 years ago) to Recent; body generally fusiform; early forms with well-developed rhomic (diamond-shaped) scales and persistent notochord; scales thinner and cycloidal (fan-shaped) in later forms; 6 families; 1 living species.

†*Order Pachycormiformes*

Lower Jurassic (about 160,000,000–190,000,000 years ago) to Upper Cretaceous (about 65,000,000–100,000,000 years ago); body fusiform, caudal fin widely forked, long snout; 2 families; Europe and North America.

Order Semionotiformes

Upper Permian (about 225,000,000–250,000,000 years ago) to Recent; 2 families of widely divergent fishes; fossil Lepidotidae with normal holostean fusiform bodies, which became relatively deep and slab sided in some members; marine and freshwater, widely distributed; gars (Lepisosteidae) are elongated, long snouted, primarily freshwater predators, extant in North America.

†*Order Pycnodontiformes*

Upper Triassic (about 190,000,000–210,000,000 years ago) to Eocene (about 38,000,000–54,000,000 years ago); upper and lower teeth modified to form crushing pavement; body nearly disk-shaped; anal and dorsal fins elongated; caudal fin externally symmetrical.

Division Halecostomi (or Halecostomes)

Relatively small; body fusiform; preopercle not buttressing the bones of the palate.

†*Order Pholidophoriformes*

Middle Triassic (about 200,000,000 years ago) to Lower Cretaceous (100,000,000–136,000,000 years ago); holosteans with some trends toward teleosts, notably: loss of ganoin from fin rays, scales, and dermal bones; loss of peg and socket joints between scales; about 7 families; marine and freshwater, of wide distribution.

Critical appraisal. According to some authorities, the Leptolepiformes, a teleost group, should be included among the Halecostomes. This opinion indicates that the boundary between the Halecostomes and the Teleostei is difficult to define. The family Pholidophoridae, in particular, has a skull pattern almost identical with that of the leptolepids; the feeding mechanisms are also quite similar. (Ed.)

The modern bony fishes, or teleosts (Teleostei)

General characteristics of teleosts

The name teleost is applied to members of the Teleostei, a diverse group (infraclass) that includes virtually all of the world's important sport and commercial fishes, as well as a much larger number of lesser known species. The infraclass is distinguished primarily by the presence of a homocercal tail; *i.e.*, one in which the upper and lower halves are about equal. The teleosts, sometimes called "advanced bony fishes," comprise some 20,000 species (about equal to all other vertebrate groups combined), with new species being discovered each year.

The great abundance of some large species, such as the tunas and halibuts, and of smaller species, such as the various herrings, have made teleost fishes extremely important to mankind as a food supply. In almost every part of the world local fishes are used as food by men at all stages of economic development. In addition to being a commercial food resource, teleost fishes provide enjoyment to millions of people and in many countries of the world support a large sport fishing industry. As aquarium subjects both marine and, especially, small freshwater teleosts provide esthetic beauty for millions of aquarists, supporting a multimillion dollar industry. Part of the interest in teleosts as aquarium subjects is derived from the great diversity of their anatomical structures, functions, and colour. Indeed, these fishes vary more in structure and behaviour than do all the mammals, birds, reptiles, and amphibians combined. Teleosts range in size from tiny gobies less than an inch long when fully adult to large marlins exceeding 3.4 metres (11 feet) in length and 550 kilograms (1,200 pounds) in weight. Another large fish, the ocean sunfish (*Mola*), reaches at least three metres (10 feet) and may weigh more than 900 kilograms (2,000 pounds).

Natural history

Different species and groups have widely varying life cycles and behaviours. Teleost fishes are adapted to widely varied habitats from cold Arctic and Antarctic oceans that remain colder than the freezing point of fresh water to desert hot springs that reach temperatures over 38° C (100° F). Usually a particular species will have a restricted temperature tolerance, often between 10° to 20° F above and below the mean temperature of its environment. In terms of physical habitat, the advanced bony fishes are adapted to a wide and interesting variety of conditions, from fast, rock-laden torrential streams in the Himalaya Mountains to the lightless depths of ocean trenches 10,670 metres (35,000 feet) below the surface, where many species manufacture their own light.

Reproductive behaviour

A species of teleost fish is usually restricted to one kind of habitat at any given stage of its life cycle. It may occupy this habitat throughout its life, or it may change habitats as it grows older. The various species living in rocky marine shores, mud flats, sandy shores, and coral reefs are usually all different, a diversity of habitat adaptation reflected in the life cycle, behaviour, locomotion, anatomy, and reproduction. Some cyprinodonts or killifishes, for example, confined to annual ponds in Africa and South America, live only the few months during the rainy season that their ponds retain water. They hatch from eggs buried in the mud, grow up, lay their own eggs in the mud in the short space of four to eight months. Such fishes are known as annuals. Others, such as the Pacific salmon, hatch from eggs laid in the gravel of cool, temperate zone streams, spend their first year growing in the streams, then enter the sea to grow and migrate for two, three, or four years, finally returning to the streams where they first grew up.

There they lay their eggs and die. Such fishes, spawning in fresh water and living most of their lives in the ocean, are called anadromous.

Many freshwater and marine teleosts lay eggs on rocks or aquatic plants, the male and sometimes the female defending the eggs and even the young against predators. Many of these fishes will live two, three, or four years or more, usually spawning in the spring in temperate regions and in the rainy season in the tropics. There are large numbers of teleosts, especially those in the ocean, whose breeding habits are unknown. Most fishes lay numerous eggs, often simply scattering them over plants or in the open ocean, where they provide food for many organisms, only a few young surviving to adulthood. Most offshore marine teleosts lay planktonic (free-floating) eggs, whereas most freshwater fishes lay demersal eggs; *i.e.*, eggs that sink to the bottom. Some teleosts, such as certain of the perchlike African cichlids, some catfishes, and some marine fishes (*e.g.*, cardinal fishes) are oral brooders, the male or female incubating the eggs in its mouth.

Some fishes, for example, some of the sea perches (Serranidae), are functional hermaphrodites, one individual producing both sperm and eggs. Self-fertilization is evidently possible in some cases, but more often the fish plays the male and female roles alternately. In some species an individual is a male during the early part of its adult life and a female later.

About a dozen families of teleosts produce living young. In some the eggs are abundantly supplied with yolk and merely hatch in the ovary (ovoviviparous), in others the eggs have little yolk, the young hatch at a relatively undeveloped state and are nourished by a placenta-like structure of the ovary (viviparous).

The behaviour of teleosts is as varied as their other attributes. Some oceanic fishes travel in close-ordered schools, seemingly responding to predation from larger fishes almost as a single organism. Larger, predatory fishes are usually solitary and hunt or wait for prey alone. Many marine shore and freshwater fishes establish territories during the breeding season, and some may travel in relatively loose schools or shoals when not breeding. Many kinds of teleosts enter into symbiotic relationships with other species of fishes and organisms, for example, a small, blind goby along the California coast lives together with a shrimp in the shrimp's cavelike tubular dwelling. The shrimp carries food to the goby while the goby keeps the shrimp's burrow clean. Many species of wrasse pick parasites from larger fishes, even entering the mouths of these fishes to clean the gill chambers. On the other hand, in South America some small catfishes, 2.5 to 10 centimetres (one to four inches) long, appear to be parasitic on certain other species of catfishes that reach lengths of over 2.4 metres (eight feet). The smaller fishes enter the mouths of the larger catfishes and feed on gill tissue. Unfortunately, little is known about the behaviour of most teleosts, but study of the details of their behaviour has been greatly increased in the last several decades.

Locomotion

Defining teleost fishes by functional morphology is hard, for they have evolved into many diverse shapes; but if a relatively simple teleost, a trout, is examined, its basic swimming motion can be determined. Forward motion is provided by bending of the body and caudal fin; waves of muscular action pass from the head to the tail, pushing the sides of the body and tail against the water and forcing the fish forward. The structure of the tail and the efficiency of the swimming mechanism is the prime character that distinguishes teleosts from other, "lower," fishes. The dorsal fin and the anal fin (a ventral median fin) are used partly to aid in stability and in turning, and partly in forward locomotion. The paired pelvic or ventral fins and the paired pectoral fins behind the head are used to help stabilize the body and to turn the fish. The fusiform shape of the trout reduces the turbulence and drag of water flowing over the fish's body, offering least resistance to the water.

The head of the fish must be adapted for feeding, breathing, and detecting prey and enemies. At the same time it must be relatively streamlined, offering as little resistance to the water as possible. The head of a trout is well formed for these functions by being fusiform but expandable, where necessary, to take in food and water. The fish forces the water in one direction, into the mouth, over the gills, and out the gill slits. Back flow is prevented by valves at the mouth and by the gill covers. The fish, however, can eject undesirable particles and water out the mouth by special action. The teleost head is efficient in having eyes and organs for the sense of smell located in optimum spots for seeing and smelling food. At the same time these organs offer little resistance to water flowing over the head.

For a complete classification of teleosts, see the *Annotated Classification* in the first section of this article; additional taxonomic information is presented in the following sections on the major groups of teleosts.

(S.H.W.)

MAJOR TELEOST GROUPS

Bonefish, tarpons, ladyfishes, and allies (Elopiformes)

The order Elopiformes contains about 12 species of marine and brackish water fishes, the best known of which are bonefish, tarpons, and ladyfishes. Most taxonomists recognize two living suborders of elopiforms: Elopoidei, which consists of two living families; and Albuloidei, which contains one living and one extinct family. A few elopiforms are prized gamefishes, but only the Pacific tarpon (or oxeye) is of economic importance as food, supporting a major fishery in Southeast Asia. The terms "ladyfish" and "bonefish" have both been used for *Elops saurus* and *Albula vulpes.* In this article the name ladyfish is applied only to *Elops* and bonefish only to *Albula.* The tarpons and ladyfishes are fast-swimming predators with adult lengths of up to 2.5 metres (approximately eight feet) in tarpons and about one metre (three feet, three inches) in ladyfishes. The bonefish and Japanese gisu are specialized bottom feeders. All except the gisu are coastal fishes of warm oceans, most common in latitudes from 20° N to 20° S.

Primitive position among teleosts

Elopiforms are of interest to the ichthyologist as the most primitive living teleost fishes, standing in much the same relation to the higher bony fishes as do the egg-laying mammals (monotremes) to other mammals. As is usual with primitive groups, the elopiforms have an extensive fossil record, with many more fossil than recent species.

GENERAL FEATURES

Despite their archaic structure, elopiforms are related by their life history to more specialized groups such as the eels. Like eels, elopiforms have a ribbonlike, translucent, pelagic larva (leptocephalus) that undergoes a striking metamorphosis involving shrinkage to about half the maximum larval size. The bonefish, tarpons, and ladyfish spawn close to shore. The eggs are shed and fertilized in shoal water, sinking to the bottom. Elopiforms are prolific breeders; a large Atlantic tarpon (*Tarpon atlanticus*) was estimated to contain more than 12,000,000 eggs, about seven times as many as in the proverbially fecund cod. The newly hatched leptocephali may be carried out to sea by offshore currents, but metamorphosis only occurs close inshore, and it is probable that larvae carried far out to sea die.

During or immediately after their metamorphosis, the postlarvae migrate inland and accumulate in brackish pools or creeks, often connected with open water only at extreme high tide. Such environments are stagnant and low in oxygen, and air breathing (see below) is an important aid to survival. The juvenile fish feed on small crustaceans, insect larvae, and other small animals, moving back to the sea as young adults. The gisu (*Pterothrissus gissu*), which differs from other elopiforms in inhabiting deeper and colder waters, is apparently an exception to this pattern of development, larval life and metamorphosis

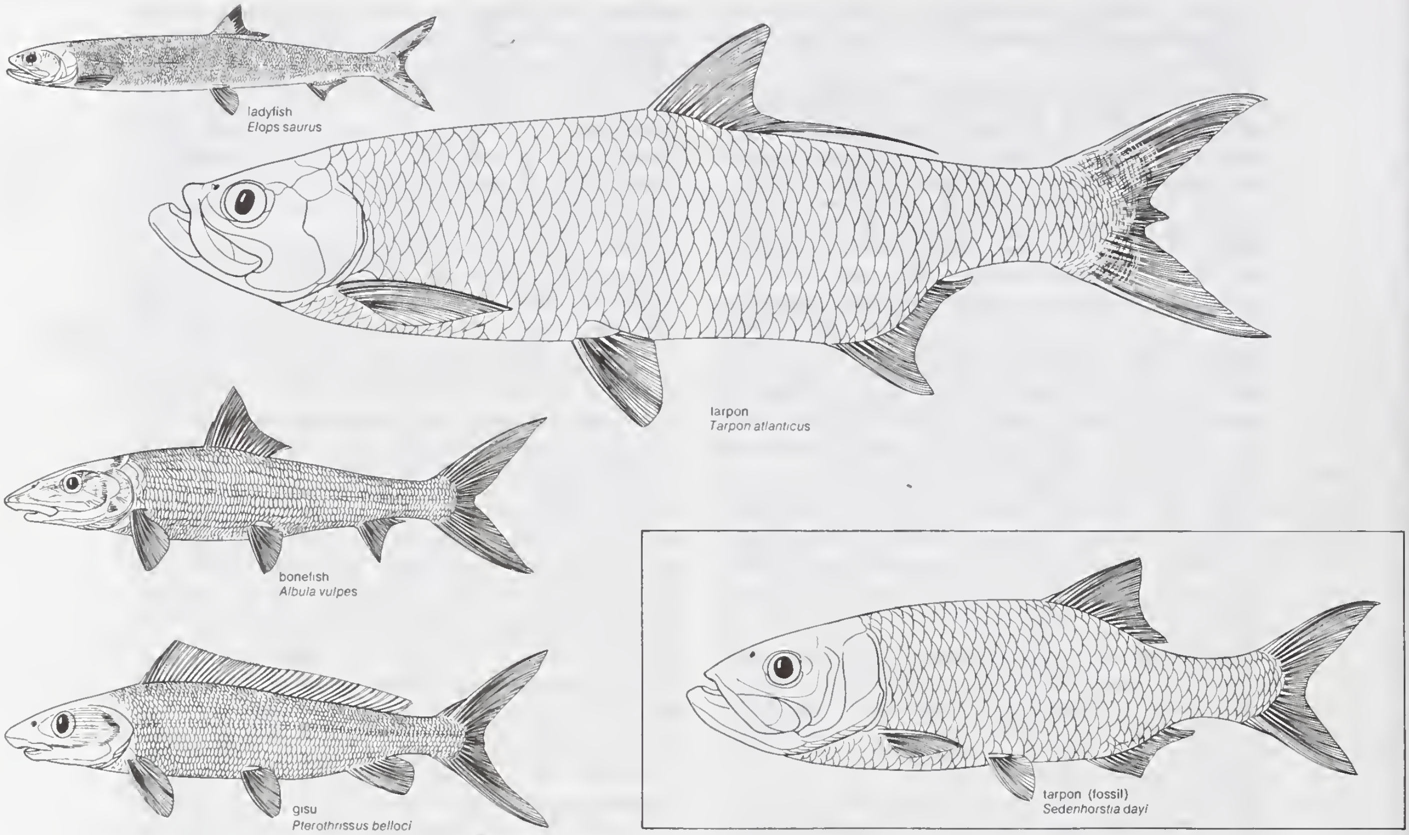

Figure 16: Body plans of several elopiform fishes.

III Teleosteens malacopterygiens, Vol IV, fasc 2, 1953, p 14 fig 5

taking place in deep water, without the postmetamorphic inland stage that is experienced by other elopiforms.

With the exception of the gisu, elopiforms are coastal fishes, able as adults to enter brackish or fresh water. Adult ladyfishes and tarpons are typical predators of coastal waters, feeding mainly on other fishes. The Atlantic tarpon is renowned for leaping out of the water; the Pacific tarpon (*Megalops cypinoides*) and ladyfishes (several species of *Elops*) behave similarly, "rolling" at the surface. The purpose of this behaviour seems to be the intake of air. Like all of the other primitive teleosts, the elopiforms possess an open duct to the swim bladder, and air that is taken in at the mouth can be passed into the swim bladder.

Behaviour related to air intake

In tarpons the swim bladder is lunglike, partially compartmented and highly vascularized. Tarpon are obligate air breathers, dying from asphyxiation if prevented from reaching the surface, an unusual condition for a species in which adults normally inhabit well oxygenated waters. Such an adaptation, however, is certainly advantageous in the stagnant pools where postlarval life is spent. The tarpons exhibit a further modification of the swim bladder, a pair of forward outgrowths that contact the auditory region of the braincase and are partially enclosed in bony bullae, a modification that presumably improves the sense of hearing.

The bonefish is a bottom feeder in shallow water along coastal areas, coming in with the tide and grubbing with its snout for worms and shellfish, which it is able to crush with its rounded palatal teeth. It can expose prey buried in the sand by directing a jet of water from its mouth. The deep-water gisu feeds mainly on worms, probably by similar methods.

PALEONTOLOGY AND CLASSIFICATION

Fossil history. The family Elopidae is the only extant teleostean family whose fossil record extends back into the Jurassic (about 140,000,000 years ago). The Upper Jurassic genus *Anaethalion* is included in this family on the basis of some forms that were extremely similar to the modern *Elops*. The genera *Notelops*, from the Lower Cretaceous of Brazil, and *Osmeroides*, widely distributed in Upper Cretaceous seas, were probably true elopids, but the allocation of numerous little-known Cretaceous genera currently placed in the Elopidae, often on the basis of negative evidence, must be considered tentative. The earliest known member of the tarpon family appears to be the fossil *Sedenhorstia*, from the Upper Cretaceous of Europe and Lebanon. Fossils assigned to *Megalops* appear in Eocene deposits. The earliest member of the extinct suborder Pachyrhizodontoidei, *Rhacolepis* (from the Lower Cretaceous of Brazil), was small and resembled the ladyfishes, but later, Upper Cretaceous, members of this group become considerably more specialized. *Pachyrhizodus*, from the Cretaceous chalks of Europe and North America, exceeded three metres in length and superficially resembled a tuna. Pachyrhizodontoids may well have been large fast-swimming predators of the open sea, a niche which is now filled by the tunas.

The genus *Albula* has been recorded in the Upper Cretaceous of North America and in the Paleocen of Europe, but typically albulid tooth plates occur in Lower Cretaceous deposits. Several Cretaceous and Tertiary albulid genera have been described on the basis of otoliths ("earstones"). *Istieus*, from the Upper Cretaceous of Germany, had characteristics that were very similar to those of the modern *Pterothrissus*.

Annotated classification.

ORDER ELOPIFORMES

Elopomorph fishes having a long but not eellike body; scales containing bone-cells; teeth on the parasphenoid bone; a transverse sensory canal across the snout; broad infra-orbital bones extending back to the operculum, 55–90 vertebrae, a primitive tail skeleton with 2 free vertebrae supporting 6–7 hypural bones, tail fin large and forked.

Suborder Elopoidei

Mouth terminal and snout unmodified; 2 supramaxillaries; many branchiostegal rays (23–35); teeth small; large gular plate between the lower jaws; 7 hypural bones.

Family Elopidae (ladyfish or tenpounder)

Upper Jurassic to Recent. Very generalized fish, the living

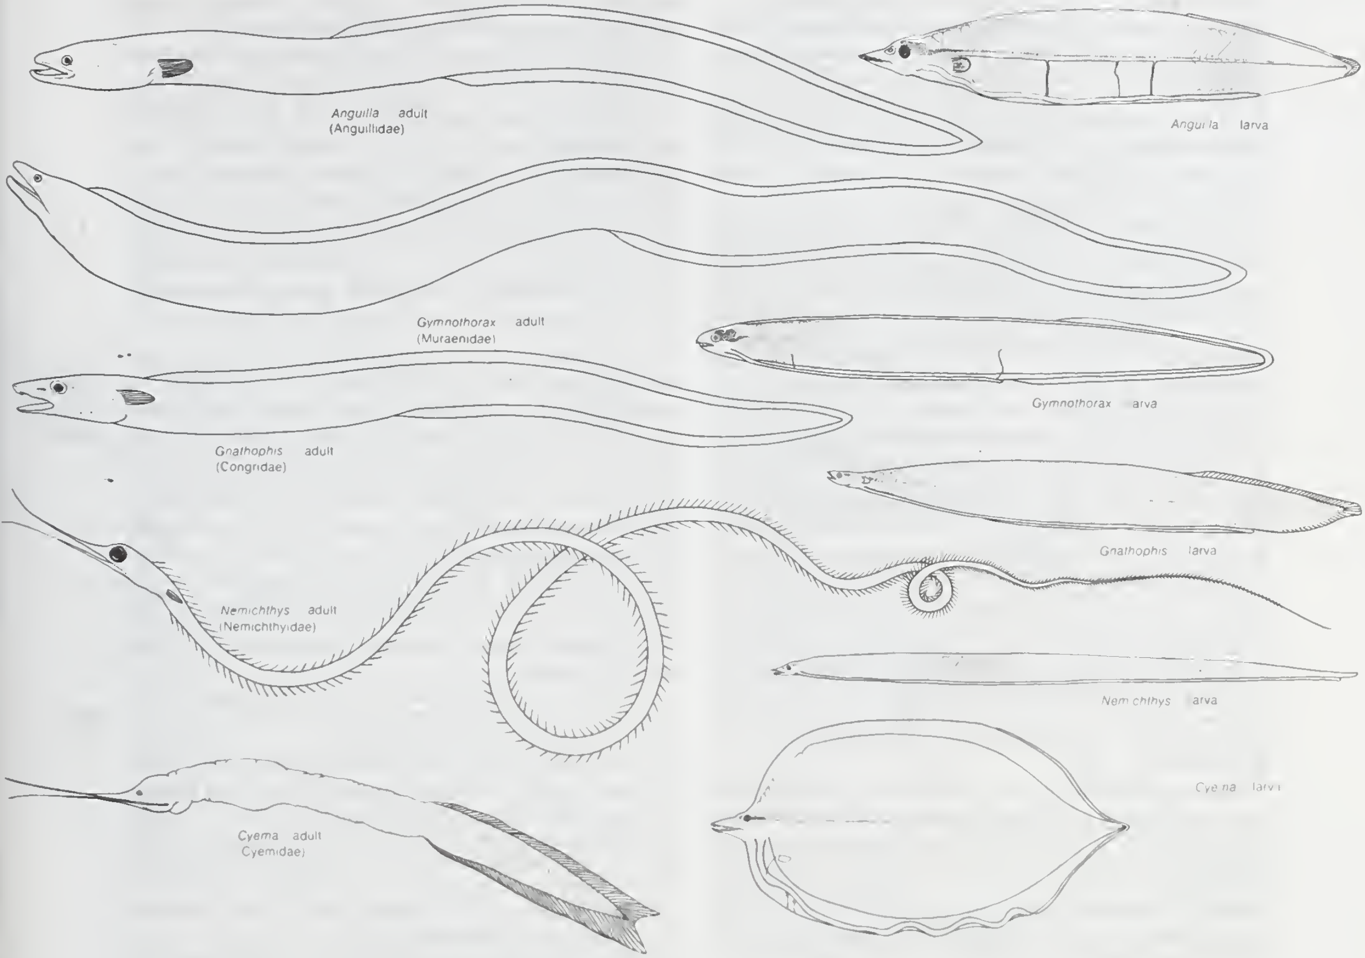

Figure 17: Adults and larvae of representative eels.

Drawing by J Helmer based on (Cyema adult) by courtesy of Carl L Hubbs from (*Gymnothorax* larva) E Herald *Living Fishes of the World*, Doubleday & Co Inc (*Anguilla* adult *Nemichthys* adult) P H J Castle World of Eels (1968) in *Tuatara* vol 16 no 2 (*Anguilla* larva *Gnathophis* adult *Gnathophis* larva) *Zoology Publications from Victoria University of Wellington* (1963) (others) *Transactions of the Royal Society of New Zealand* (1965)

forms having 32–35 branchiostegal rays and the swim bladder unmodified. Length to 0.9 m (about 3 ft); weight to about 13 kg (28½ lb). One living genus, *Elops*, with 5 or 6 species, circumtropical. Numerous fossil genera.

Family Megalopidae (tarpons)
Swim bladder partially cellular, lunglike, and connected with the ear; scales large; 23–25 branchiostegal rays. Two living genera, *Megalops* and *Tarpon*, each with one species, recently shown to differ in the ear to swim-bladder connection. *Tarpon* confined to the Atlantic; *Megalops* to the Indian and Pacific oceans, ranging from Africa to the Philippines. *Tarpon* length to 2.5 m (about 8 feet), weight to 150 kg (about 330 lb); *Megalops* to 1.5 m (5 ft).

†Suborder Pachyrhizodontoidei
Fossil; Lower to Upper Cretaceous. Parietal bones separated by supra-occipital; gular plate absent; teeth large, pointed, and set in deep sockets. Length to 3 m (10 ft).

Suborder Albuloidei
Snout enlarged; mouth small and underslung; crushing teeth on palate; single supramaxillary bone; gular plate small or absent; 6 hypural bones.

Family Albulidae (bonefishes and gisu)
Upper Cretaceous to Recent. Characteristics those of suborder. Two living genera: *Albula* (2 species) and *Pterothrissus* (2 species). Length to 70 cm (28 in.), weight to about 6.5 kg (14½ lb). *Albula* inhabits coastal waters, *Pterothrissus* deeper waters (below 200 m [650 ft]).

†Family Phyllodontidae
Fossil. Upper Cretaceous and Early Tertiary. Known only from thick tooth plates, with many superimposed series of replacement teeth. Five genera: from Africa, Europe, and North America.

Critical appraisal. The chief problem in defining and classifying the elopiforms is the reliance on primitive features, which are merely negative evidence against relationships with other, more advanced groups. Similar problems arise among the most primitive members of all animal groups. The possession of a leptocephalus larva places the elopiforms as the basal order of the cohort Elopomorpha, which also contains the eels, halosaurs, and notacanths. But it is only on negative evidence (absence of specializations) that the elopoids and albuloids are associated, and the absence of any notable specializations in elopoids makes the placing of fossil forms in this group rather doubtful. (C.P.)

Eels (Anguilliformes)

True eels are elongated or even wormlike bony fishes of the order Anguilliformes and include the common freshwater eels as well as the voracious marine morays. Only the freshwater eels (family Anguillidae), which are in places abundant and greatly valued as food, are of major economic importance. Regardless of their final habitat, all eels probably pass through an extended larval phase (leptocephalus) in the open ocean. They undergo metamorphosis to a juvenile stage that is a smaller version of the adult. At maturity, eels range from 10 centimetres (four inches) (in the deep sea *Cyema atrum*) to 3.5 metres (11½ feet) (in the moray *Thyrsoidea macrura*). They occur to considerable depths in most oceans and are greatly diverse in tropical seas. They range in colour from drab gray or black (in deep sea species) to colourful and patterned (in tropical reef species).

NATURAL HISTORY

Eels have a remarkable life cycle. Broadly, it consists of development and early growth in the open ocean: the planktonic (free-floating) dispersal of eggs and larvae, Life cycle metamorphosis, juvenile and adult growth, and the migration of maturing adults to an oceanic spawning area. Eels share the leptocephalus phase with several other orders (Elopiformes, Saccopharyngiformes, and Notacanthiformes). A prolarva, hatching from a relatively large egg (up to 2.5 millimetres [about $^{3}/_{32}$ inch] diameter), rapidly becomes a leaflike leptocephalus, which floats in the surface layers of the open ocean for as long as $2^{1}/_{2}$ years before metamorphosing.

Although the leptocephali were once thought to have been fishes of a distinct group, their relationship with the Anguilliformes was soon recognized from transitional specimens that showed larval and adult characters. They proved so difficult to identify, however, that new larval types were named as species of the genus *Leptocephalus* (though they cannot actually be considered different species from the adults that produced them), accounting for the several hundred forms known.

Leptocephali are not uncommon in the upper 500 metres (roughly 1,600 feet) of the ocean, a distribution that may be associated with the availability of food (diatoms and minute crustaceans). Their predators include various pelagic fishes. In tropical eels larval life is possibly four to six months, but temperate species may spend upwards of a year as larvae. During this time leptocephali, in the presence of suitable currents, may disperse widely from the adult spawning area. Working on massive collections of larvae from 1905 to 1930, a Danish biologist, Johannes Schmidt, established the early life history of the European and American freshwater eels. Although parts of his work have been questioned, his description of a western Atlantic spawning and a trans-Atlantic dispersal of leptocephali of these eels still stands.

After reaching full growth, the larva begins a rapid metamorphosis in which the following progressive changes are typically involved: the body becomes cylindrical and greatly reduced in bulk, perhaps by as much as 90 percent by weight; the anal vent advances from its subterminal position to about the midpoint; larval teeth are lost; the snout becomes rounded; the dorsal fin originates farther forward; and the larval melanophores (black pigment cells) disappear. Other changes, such as the loss of the pectoral fins or a reduction of body length, may also occur.

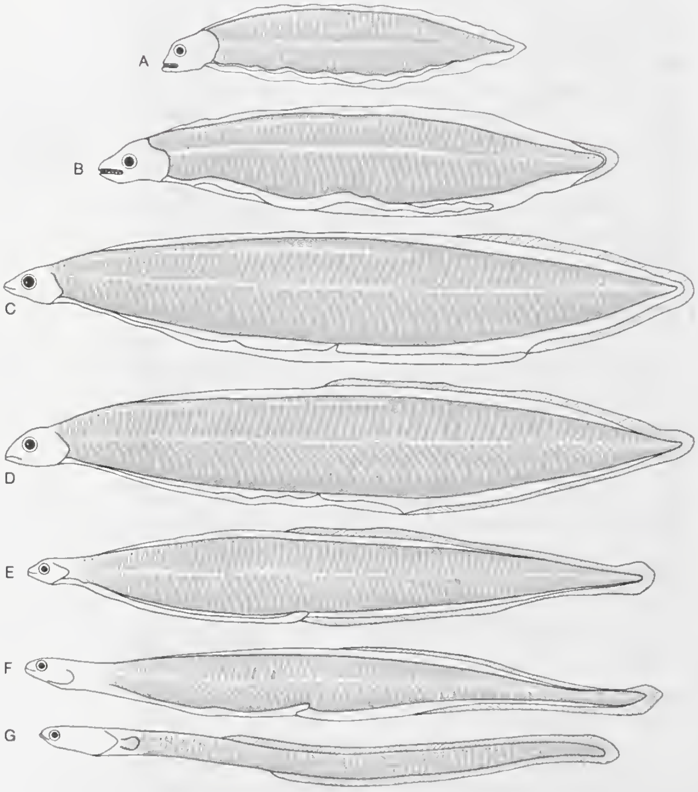

Figure 18: *Metamorphosis of the American eel.*
(A–C) Larvae or leptocephali of various sizes. (D–F) Larvae in the process of metamorphosis. (G) Glass eel, mature stage.

Leptocephali are markedly unlike their adults and the metamorphic changes are so great that a fundamental problem arises in the correlation of the great variety of known leptocephali with their adults. Metamorphosis has been followed through in aquariums and deduced from progressive growth series in plankton samples. Certain characters survive metamorphosis and are important in the recognition of eel species. These include the number of muscle segments (myomeres); the development of dorsal, anal, and caudal fin rays; and the relative positions of the renal vessels and gallbladder. In many leptocephali, the larval melanophores also remain into the juvenile (or elver).

The process of metamorphosis

Metamorphosis involves physiological and behavioral as well as structural changes, particularly those related to the assumption of a deep-sea, shallow-water, or freshwater mode of life. Metamorphosis is the mechanism by which the leptocephalus, after a period of growing, feeding, and competing with other similarly organized planktonic animals, can enter a markedly different habitat, where body shape, differentiated feeding mechanisms, sense organs, and body coloration, play an important role in survival. Metamorphosis in all eels is probably completed in the open ocean. The annual invasion of freshwaters by *Anguilla* elvers is a locally well-known process; it occurs during October–March in Europe and in spring in other temperate regions.

During several years' growth to maturity, eels are essentially carnivores, feeding diversely on planktonic or benthic (bottom-living) animals. Maturity is reached after about 10 years in the European freshwater eel but possibly much earlier in tropical marine species. The process of growth and maturation has been most closely studied in the European freshwater eel. In this species both sexes pass through successive phases of neutrality, precocious feminization, and juvenile hermaphroditism prior to becoming definitively male or female, the sex being mainly determined by environmental factors.

All eels apparently undergo a short or long distance migration at maturity to a spawning area within the area of adult distribution (in most tropical marine eels) or some distance from it (temperate Anguillidae and Congridae). These areas are generally located over the continental slope or in ocean basins some distance offshore.

During their juvenile and adult life, most eels are solitary fishes, swimming slowly by means of sinuous lateral movements of the body and median fins. Some species burrow rapidly, using a pointed tail and backward body movements. Morays and congers inhabit rock crevices, while certain congrids (Heterocongrinae) form vast colonies of several hundred individuals in tropical reef areas.

FORM AND FUNCTION

An eel is distinguished externally from most other fishes by its elongated body, which is seldom laterally compressed. A continuous dorsal, anal, and caudal fin runs around the tail tip; pelvic fins are always absent; and gill openings are usually reduced. The body covering is usually scaleless. Minor departures from this overall body plan occur in the various eel families and are correlated well with different modes of life.

Typically, a leptocephalus is elongate, laterally compressed, transparent, and gelatinous, with prominent, W-shaped myomeres and sharp, forwardly directed larval teeth. At full growth, eel larvae are five to 10 centimetres (roughly two to four inches) but may be much larger (45 centimetres [about 18 inches] in the case of the snipe eel *Nemichthys scolopaceus*). Leptocephali are at least as diverse morphologically as their adults: some are filamentous, while others are deep-bodied, even resembling a small dinner plate in shape and size.

Pectoral and median fins are present in most leptocephali but may disappear during metamorphosis. Eyes are usually normal in shape but are occasionally telescopic, and the rostrum (an anterior beaklike projection) may be greatly extended forward from the snout. The attenuate viscera are located along the ventral aspect, below the myomeres.

There is usually a straight, unmodified intestine, and the anal vent is often forward of the tail. In some families the larval gut is swollen or festooned at various points along its length, a modification of unknown significance. A long liver, with a well-defined gallbladder, occurs anteriorly on either side of the intestine. The developing adult kidney lies at about midlength. The organs are supplied and drained by many vertical blood vessels, of which the last one or two are the largest. The position of the last of these vessels equates well with the division between precaudal and caudal vertebrae and indicates the approximate position of the adult kidney.

In most leptocephali melanophores occur almost anywhere on or in the body. These vary from minute and compact to large and irregularly shaped, often distributed along the gut and laterally in a variety of patterns.

In adults there is a strong tendency towards a reduction or loss of fins and a streamlining of the profile, sometimes also with an attenuation of the body. The gill region is variously elongated by a posterior displacement of the gill arches, accompanied by separation of the pectoral girdle from the cranium. There are well-developed pharyngeal tooth plates, and the pharynx has assumed an important function in the movement of food into the esophagus. It also serves as an effective pump in the virtual absence of suction by the gill covers (opercula) for the passage of the respiratory current. The opercular series is much reduced, although numerous curved branchiostegal rays (internal gill supports) are strongly developed to support the long throat wall. Respiration through the skin is important in *Anguilla* and probably also in other eels.

EVOLUTION, PALEONTOLOGY, AND CLASSIFICATION

Studies of the few known fossil eels and the comparative anatomy of adults and larvae suggest that eels arose in the Cretaceous Period from two or more types that had at least some characters of the Elopiformes (tarpons, bonefishes, etc.).

Distinguishing taxonomic features. The important characters in determining the taxonomic ranking of eels include: the number and arrangement of myomeres and fin rays; the relative positions of mouth, nostrils, gill openings, renal vessels, and gallbladder; and the number and arrangement of teeth, skull bones, and vertebrae. Also important in identification are larval structures and pigmentation patterns.

Annotated classification. The classification used in this article is a synthesis of the work of many authorities. It is certain to be further modified as more is learned about some of the little-known families.

ORDER ANGUILLIFORMES

Elongated, bony fishes of streamlined profile; continuous median fin with up to 650 soft rays; pelvic fins absent; reduced cycloid scales (*i.e.*, with skin-covered bone overlying a layer of fibrous connective tissue) sometimes present; swimbladder with duct; cranial bones reduced, particularly the palatoquadrate and opercular series; pectoral girdle detached from cranium; vertebrae up to 700, with fused centra and arches; a leptocephalus larva. There are 19 families, about 140 genera, and more than 500 species. One family in freshwater; the remainder marine, in all oceans, mainly tropical Atlantic and Indo-Pacific, to considerable depths.

Suborder Anguilloidei

Frontal bones of skull paired, supraoccipital present.

Family Anguillidae (freshwater eels)

Worldwide, but not on Pacific coast of America and south Atlantic coasts. Scales present, gill slits ventrolateral. Important as food.

Family Heterenchelyidae

Tropical Atlantic. No fins, mouth large.

Family Moringuidae (worm eels)

Tropical Indo-Pacific and western Atlantic. Anus in posterior half of body, degenerate, burrowing.

Family Xenocongridae (false morays)

Pantropical. Burrowing.

Family Muraenidae (morays)

Pantropical to subtropical. No pectorals, large mouth, often brightly coloured, voracious, sedentary.

Family Myrocongridae

South Atlantic. Laterally compressed, poorly known.

Suborder Nemichthyoidei

Frontals paired or fused, supraoccipital present or absent, paired nostrils close in front of eye.

Family Nemichthyidae (snipe eels)

Bathypelagic (deepwater), worldwide. Jaws greatly extended, minute teeth.

Family Serrivomeridae (sawtooth snipe eels)

Bathypelagic, worldwide. Jaws moderately extended; bladelike teeth on vomer bones.

Family Cyemidae (bobtail snipe eels)

Bathypelagic, worldwide. Jaws extended, body truncated.

Suborder Congroidei

Frontals fused, supraoccipital present.

Family Congridae (congers)

All oceans to considerable depths.

Family Muraenesocidae (conger pikes)

Pantropical. Large teeth, voracious.

Family Nettastomatidae (witch eels)

Deepwater. No pectoral fins.

Family Nessorhamphidae (duckbilled eels)

Bathypelagic. Duckbill snout.

Family Derichthyidae (neck eels)

Bathypelagic. Short snout.

Family Ophichthidae (snake eels)

All oceans, many branchiostegals, caudal reduced or absent.

Family Macrocephenchelyidae

Deepwater, Pacific. Rare.

Suborder Synaphobranchoidei

Frontals fused, supraoccipital present, 3rd hypobranchial directed backward, larva telescopic-eyed.

Family Synaphobranchidae

Deepwater, worldwide. Gill slits ventrolateral to ventral, united. Scales present.

Family Simenchelyidae (parasitic eels)

Deepwater, worldwide. Semiparasitic, mouth transverse, scales present.

Family Dysommidae

Deepwater, worldwide. Anus near pectoral region. No scales.

Critical appraisal. The eels were early split into the Colocephali (morays) and Enchelycephali (others). Later the suborder Carenchelyi was added (for the Derichthyidae). Two fundamental but undesignated groups, separated on the poorly evaluated character of fused versus separate frontal bones, have been considered the main evolutionary lines, forming the suborders Anguilloidei and Congroidei. In the absence of a workable alternative this division must stand. In 1940 L.S. Berg added the Nemichthyoidei, the subordinal position of which requires further investigation. Various osteological and larval characters suggest that the Synaphobranchoidei, as recently recognized, may truly represent a further lineage. Some would include still another suborder, the Saccopharyngoidei. These strange deep-sea fishes, while closely related to true eels, appear distinctive enough to merit separate ordinal rank as the Saccopharyngiformes.

The limits of the 19 living eel families are now broadly defined. However, their interrelationships and the existence of subordinal groupings will only be firmly established by an overall survey of a range of characters and not only of specific structures throughout the order. Rare forms need investigations and larval characters require consideration. Closer study is needed of environmental effects on segmental features, and fundamental questions of species nomenclature have yet to be settled. (P.H.J.C.)

Herrings, anchovies, and allies (Clupeiformes)

The order Clupeiformes, containing some of the world's most numerous and economically important fishes, includes more than 400 species, about 20 of which provide more than one third of the world fish catch. They are by far the most heavily exploited of all fish groups. Most

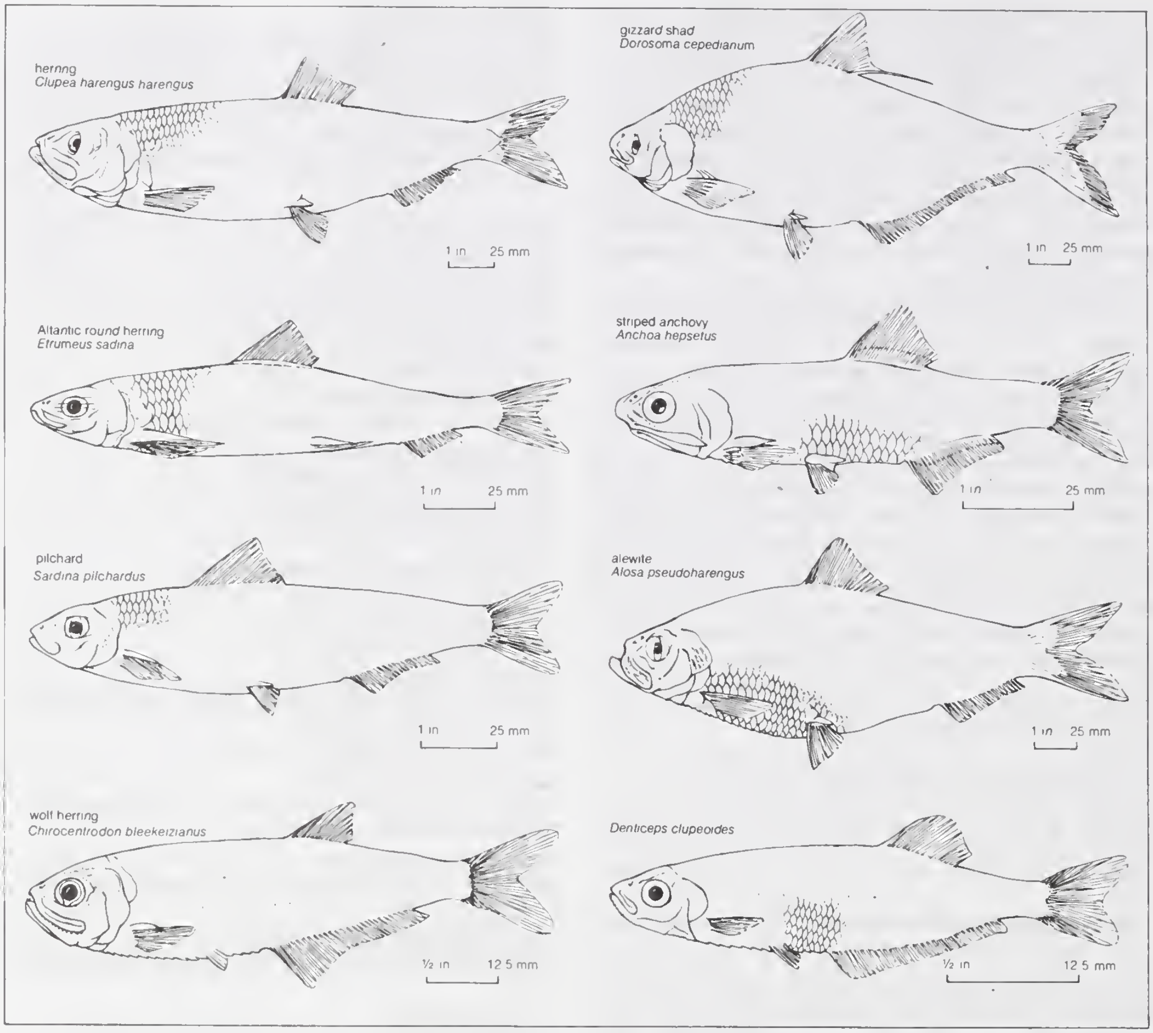

Figure 19: Body plans of representative clupeiform fishes.

Drawing by A. Murawski based on (*Clupea harengus, Etrumeus sadina, Anchoa hepsetus, Alosa pseudoharengus*) A.H. Leim and W.B. Scott, *Fishes of the Atlantic Coast of Canada* (1966), Fisheries Research Board of Canada reproduced by permission of Information Canada, (*Denticeps clupeoides, Chirocentrodon bleekerzianus*) *Bulletin of the American Museum of Natural History* (1966), (*Dorosoma cepedianum*) D.S. Jordan, *A Guide to the Study of Fishes*

clupeiforms are small marine fishes, under 30 centimetres (12 inches) in length, slender, streamlined, and rather nonspecialized in body form; a few species exceed 50 centimetres in length. The wolf herring, *Chirocentrus dorab,* is exceptional in size among the clupeiforms; this species reaches 3.6 metres (12 feet).

Authorities disagree on many aspects of the classification of the order Clupeiformes, which is usually described as including more families than are treated in this article. In a sweeping revision of the bony fishes, the ichthyologists P.H. Greenwood of Great Britain and Donn E. Rosen, Stanley H. Weitzman, and George S. Myers of the United States have restricted the order to the families Clupeidae (herrings, sardines, and allies), Engraulidae (anchovies), Chirocentridae (wolf herrings), and Denticipitidae, a single, little known African species. The last two families are of purely scientific interest; the dominant members of the order, in abundance and therefore in economic importance, are the herrings, sardines, pilchards, menhadens, sprats, anchovies, and anchovetas. Other fish groups formerly included in the Clupeiformes are the tarpons and bonefishes; salmons, trouts, and pikes; and bony tongues and mormyrs.

Distribution

Most clupeiforms inhabit more or less offshore open waters in abundant schools. Although usually considered pelagic (inhabiting the open ocean), in relation to distribution and life history, they are closer to the neritic (coastal) fauna because they do not usually occur in the really open parts of the oceans; rather, they stay close to shore and in bays. Even the truly pelagic and migratory species spawn close to shore. The geographical distribution of the order is limited mainly by temperature and salinity. About 70 percent of the species occurs in tropical waters, only few visiting subtropical regions. More than 20 species are limited to purely boreal and subarctic distribution. Remarkably few species are found in the Southern Hemisphere. In relation to salinity clupeiform fishes represent a fairly mixed group: most of them, approximately half of the living species, are wholly marine; a smaller part are anadromous (living in the sea but entering freshwater to breed); and nearly the same number are wholly freshwater fishes. The order includes some marine genera with large numbers of species, such as *Sardinella* and *Harengula,* which together comprise more than 60 genera and nearly 220 species. There are fewer anadromous clupeids, about 10 genera with 40 species, distributed mostly in temperate regions, but some in subtropical areas. Freshwater clupeiform fishes include 31 species in 16 genera, most of them limited to the tropics. Nine genera with 15 species inhabit the rivers and lakes of Central and West Africa; six species are distributed in freshwaters of the Indo-Malayan Archipelago and Australia; two genera with four species occur in freshwaters of India; some species of the genera *Sigualosa* and *Dorosoma* occur in Central America; and single species of otherwise marine genera are found in the Amazon River (*Rhinosardinia amazonica*), in the rivers of Borneo (*Ilisha macrogaster*), and in freshwater lakes of the Philippines (*Harengula tawilis*). A few other species occasionally occur in freshwater.

Of the families and subfamilies of the Clupeiformes, the subfamilies Dussumieriinae (round herrings), Clupeinae (typical herrings), and Pristigasterinae, and the family Chirocentridae are purely marine; the Denticipitidae and Pellonulinae are limited to freshwater; the Alosinae (shads and alewives) and Dorosomatinae (gizzard shads) are anadromous, freshwater, brackish, or marine; and the Engraulidae are brackish or marine.

NATURAL HISTORY

It is virtually impossible to make a general statement about the biology of clupeiform fishes, except to say that it varies greatly from one species to another. The life history of the majority of species remains little known. Species of economic importance have been extensively studied in order to discover the biological peculiarities that have the determining roles in abundance and distribution; knowledge of such characteristics, of course, is necessary for efficient fishing.

Spawning habitats

Reproduction. Most clupeiforms lay their eggs near shore, often close inshore or in fjords and bays. Few clupeiform species spawn far from shore or in the open sea, except, notably, the Atlantic herring, which spawns on offshore banks. The majority of the spawning grounds are limited to shallow waters ranging from slightly below mean low-tide level to a depth of about four metres (about 13 feet). Some forms, such as the Atlantic herring, however, do spawn at depths of 40 to 200 metres (approximately 130 to 660 feet). The bottom of the spawning grounds, especially those of species with sticky eggs, tends to be clean, hard, and covered with gravel and sand. Spawning takes place above a soft, muddy bottom only if there is a vegetative cover. The freshwater and anadromous clupeiform species spawn in currents of riverbeds with a low mineral content, in shallows of big lakes, and (less often) in river arms and riverine lakes.

The majority of clupeiform fishes have pelagic (free-floating) eggs, which float in the surface or bottom water layers. Egg position is maintained by the presence of a large swollen space between the egg itself and the outer membrane. Some forms (*Clupea, Pomolobus*) have sticky eggs with an adhesive secretion, so that they stick to stones, gravel, or plants shortly after being released. Freshwater and anadromous clupeiforms usually have eggs slightly heavier than water. Such eggs, which would normally sink to the bottom, are constantly lifted by the slightest current and turbulence resulting from wave action and convection of the water. In rivers they freely drift downstream above the bottom. Only a few freshwater forms, such as the freshwater sardine (*Clupeonella abrau*), have eggs that develop in the surface water.

The number of eggs produced varies greatly, but, in general, smaller species produce few eggs, larger species produce many. One of the smaller sprats (*Sprattus sprattus phalericus*), with a maximum size of eight centimetres (about three inches), produces about 2,000 eggs; one of the biggest shads, *Alosa kessleri kessleri*, can produce more than 300,000 eggs; and menhaden (several species of *Brevoortia*) produce more than 500,000. Freshwater species usually have more eggs than marine species of comparable size, evidently an adaptation against the higher mortality in riverine conditions. Those species of clupeiforms with adhesive eggs produce more eggs than do those with free-floating eggs. Apparently, eggs that develop sticking to the bottom have a much higher mortality rate from predators than do eggs that develop floating in the surface water. Of great importance in reducing mortality rates is "repeated portion" spawning: in the majority, if not in all, clupeiform fishes, the eggs in the gonads do not become ripe all at once but in two or more portions, allowing more eggs in the limited space of the body cavity and enhancing the chances of some surviving if the first are destroyed. The many causes of spawn mortality range from those of a physical character, such as wave action and sudden temperature drops, to biological ones, such as predation by gulls and ducks. An important protective mechanism against destruction of the abundant schools is the remarkably early age at which they first breed; females begin frequently to spawn only a few months after hatching. This, coupled with high fecundity, gives the order a high reproductive potential.

Variation in hatching times

The duration of egg development varies from a few hours to nearly two months. An important factor in the rate of development is the temperature of the surrounding water; the cold-water herrings have the longest developmental period. The egg development of the Atlantic herring takes as long as 47 to 50 days at a temperature of 0.1° C (just above 32° F) but only eight days at 19° C (66° F). Some shad eggs develop in about 75 hours at 17° C (63° F) but require only 49 hours at 19° C. The eggs of the Tanganyika sardine (*Stolothrissa tanganicae*), an open-water, freshwater, surface spawner, hatch in 24 to 36 hours while constantly sinking from the surface to a depth of 75 to 150 metres at 25° C (77° F).

Growth and mortality. The thin, threadlike, newly hatched larva has a shape characteristic of nearly all clupeiform fishes, but its behaviour varies greatly, depending on the habitat. In marine species such as the Pacific herring (*Clupea pallasii*), the larvae, shortly after hatching, tend to be concentrated near the surface and usually stay a long time in the area of the spawning ground. The larvae of the Atlantic herring at first tend to make short, upward movements from the spawning beds on the bottom, then sink back again. They start to make horizontal movements within two hours after hatching and after six hours start to form swarms. As their length increases, the vertical movements become more and more pronounced, particularly at night. Larvae have been found to be dispersed by currents at depths of from one to 600 metres (roughly three to 2,000 feet). Later, juveniles drift with the current on the surface, sometimes as far as 1,300 kilometres (slightly more than 800 miles). The larvae of the Tanganyika sardine, less than two millimetres (0.08 inch)

Scott, *Fishes of the Atlantic Coast of Canada* (1966), Fisheries Research Board of Canada, reproduced by permission of Information Canada, and (adult *Anchoa mitchilli*) A.J. Mansueti and J.D. Hardy *Development of Fishes of the Chesapeake Bay Region An Atlas of Egg, Larval, and Juvenile Stages*, by the Natural Resources Institute, University of Maryland

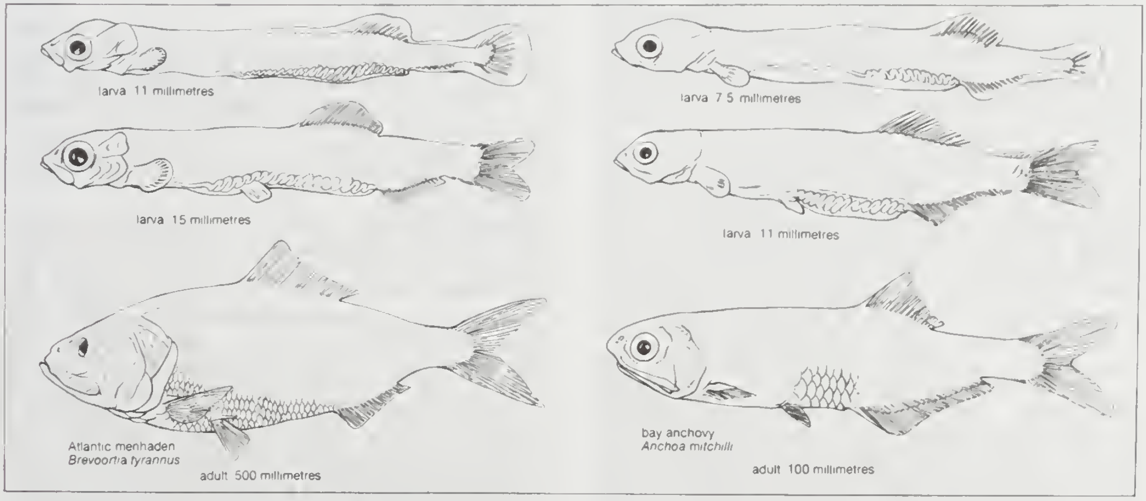

Figure 20: Changes in body proportions and fin position between larvae and adult in two clupeiform fishes.

long, tend after hatching to come straight up by swimming movements of the tail, which is the only flexible part of the body; they sink, however, as soon as they stop movement. Such vertical movement is vital, because the larvae would not survive were they to sink below the level of oxygenated water (80–200 metres [roughly 260–650 feet]). As they grow, the larvae gradually move to the surface waters; when they are about five to six millimetres long, they move toward the shore. They form schools when about 10 millimetres (0.4 inch) in size. In the riverine-spawning Atlantic menhaden (*Brevoortia tyrannus*) the newly hatched pelagic larvae first drift downriver between fresh and brackish water and shoreward from spawning areas and into estuarine nursery areas. Later, pelagic juveniles tend to move upstream as far as 50 kilometres (31 miles), emigrating into the sea only after nearly one year.

Causes of larval mortality

In the early stages of life, all clupeiforms are subject to a high mortality rate, by predation of larger fishes, birds, comb jellies (ctenophores), and arrowworms (chaetognathans) and by being carried out of sheltered bays into localities in which the proper food is lacking. Mortality has been estimated at well over 99 percent, but, because of the extremely high fecundity, the distribution, and the early maturity, the recruitment of new breeding individuals remains high. The age of first sexual maturity is seldom more than three years, and the length at maturity rarely exceeds more than 15 centimetres (approximately six inches). Late-spawning species are usually larger and move over long distances. The age at first breeding is broadly correlated with rate of growth of the individual and with maximum length attained by the species, but there are other determining factors, some of which are unknown. The Siberian shad (*Alosa saposhnikovi*), Baltic sprat (*Sprattus sprattus balticus*), and the *Clupeonella engrauliformis* all mature at two to three years of age but at lengths of 160 to 200 millimetres (roughly 6¼ to 8 inches), 120 to 130 millimetres (4¾ to 5 inches), and 85 to 100 millimetres (3 5/16 to 4 inches), respectively. Different populations of a species may vary in their growth rates; the races of the Atlantic herring vary from two to seven years in age at maturity and from 100 to 185 millimetres (4 to 7¼ inches) in length at maturity. Members of anadromous populations of the alewife (*Alosa pseudoharengus*) reach maturity at three to four years of age and 150 to 170 millimetres (roughly 6 to 6¾ inches) in length, but those of landlocked populations breed at one to two years of age and 95 to 100 millimetres (3¾ to 4 inches).

Migration. During their life cycle some clupeiforms undertake very long migrations of several thousand kilometres; others live in a more or less circumscribed area. Such differences occur, however, even within a species; some races of the herring, for example, spend their entire lives in more or less limited areas; others undertake some of the longest known migrations. Some forms of the Caspian shad (*Alosa caspia*) remain all year round in the southern region of the Caspian Sea, but others move long distances from winter habitats in southern parts to spawning grounds in the northern region of the Caspian.

In addition to spawning migrations, some species travel long distances for feeding. Japanese pilchards (*Sardinella sagax melanosticta*) winter and spawn in the southern part of the Sea of Japan and on the Pacific side of the southern islands of Japan, then move in early summer to the northern end of the Tatar Strait and, in warm years, even to the eastern shore of the Kamchatka Peninsula. Similar or even longer migrations are made by the Californian pilchard or Spanish sardine (*Sardinella anchovia*) and others. Most of these spawning and feeding migrations are from south to north and occur along the coast with the aid of some of the larger ocean currents. As the fish move fairly close to shore, they become the object of intensive fishing.

Long-distance movements of herring

Some of the longest migrations extend over several years and start in the larval stages. The majority of the young Pacific herring spend part or the whole of their first year in shallow coastal waters. Larvae of the Murman race of Pacific herring and Norwegian race (or spring race) of North Atlantic herring usually hatch on offshore spawning grounds and start their long journey drifting with the currents. Those of the Murman race drift with the North Atlantic Current along the coast of northern Norway, north and east, and later, as juveniles, spread actively into the Barents Sea and even into the White Sea. After their first spawning, the Murman herrings move north to the waters around Spitsbergen. The movements of the Norwegian spring herring are similar to those of the Murman race. The young herrings move into deeper water and, as they grow bigger, move farther and farther from the coast. While still immature, they are taken by fisheries in Norway, Denmark, and Scotland and are processed for oil and into meal. As a rule, migrations are oriented by the sea currents near the spawning grounds, but the fish go as well with or against the current direction; four forms of the Caspian shad are known to move against currents.

Food ecology. Intensity of movement and feeding habits determine the relative abundance of various species of clupeiform fishes; these same factors determine economic importance. All of the abundant (and economically important) species feed on plankton—pelagic protozoans (diatoms and flagellates), copepods, metazoan larvae, euphausids, and amphipods. Some apparently feed all year round, as long as food is available, but most change their feeding habits seasonally. It is known that all forms of the herring and most members of the genera *Alosa* and *Clupeonella* do not feed during the spawning season; feeding is most intensive in the summer after spawning and less so in spring before spawning.

Factors affecting abundance

Predatory clupeids seem to be relatively scarce and usually have a much smaller commercial value than do the plankton feeders. The fish-eating race of Russian shad *Alosa kessleri kessleri,* for instance, is far less abundant and is caught less often than is the plankton-feeding race *A. k. volgensis.*

Some evidence suggests that even among plankton-feeding clupeiform fishes, while some species are as a rule abundant, many others are more or less rare. This variation is apparently primarily determined by the size of the inhabited area and the size of spawning grounds; of secondary importance are the time and distance of migrations preceding the age of first reproduction. The Pacific sardine (*Sardinops sagax*)—which inhabits vast areas on both sides of the North Pacific, the South Pacific coasts of South America and Australia, and the Indian Ocean coasts of Australia and Africa—is a good example of a widespread, highly migratory, and economically important species; the herring *Clupea harengus* provides a similar example. Most of the Pacific races of herring, on the other hand, are local and nonmigratory, and their role in commercial catches is far below the value of the Atlantic races. The Japanese pilchard is known to feed in southern as well as in northern regions, and from the ecological point of view this whole area of the Pacific is fully utilized. The high abundance of anchovies is determined more by their early age of sexual maturity than by their movements; similarly, the relatively high abundance in a restricted habitat of the Tanganyika sardines appears to stem from precocious breeding.

The size of the inhabited area is reflected in the presence of more progressive adaptive morphological characteristics. All of the clupeiforms with more primitive features (*e.g., Denticeps, Dorosoma, Clupeonella*) are less abundant and are limited to small areas. Tropical genera have more different species; subtropical and temperate genera are more often monotypic (comprising a single species) but far more abundant.

Schooling behaviour. With few exceptions, the important behavioral characteristics of clupeiforms are schooling and diurnal (daily) vertical movements. Schools are formed with larvae or young juveniles. A fish less than 10 millimetres long approaches the tail of another; both vibrate their bodies in a series of rapid motions, after which they swim together. Occasionally, they are joined by others, and, as the fish grow a few more millimetres in length, the first small schools increase in size and begin to show a steady schooling pattern. Opinions differ on whether the school keeps together through visual contact—it sometimes tends to break up at night—or through sensations received by the lateral-line system, a series of sensory endings extending along the side of the fish. When the schools do persist after nightfall, the lateral-line system may also play a significant role in preventing one animal from straying.

Size, shape, and arrangement of schools

Single schools of herring or anchoveta have been estimated to include many millions of individuals, and some authorities assert that as many as 3,000,000,000 fish may occur in a single school. Even a big school such as this behaves as if it were one organism, with a roughly spherical shape, which is flattened when the school comes into shallow waters or approaches the surface. Within a school of anchovies, the larger individuals tend to be below, the smaller ones above, so that light is allowed to filter through the whole school. There are limits to the size of individuals in any big school; for herring, the difference between the largest and smallest members of a school is about 50 percent. Fishes above or below the size limit break away and form schools among themselves, but even large uniform schools occasionally break apart, and small schools may fuse into larger units. The uniform size of individuals within a school (mostly the same age group) is of great convenience to man, as the fish sort themselves out naturally for canning.

Within the school each fish usually is spaced evenly with enough room between it and the others to swim but not to turn around. In all schools of some species, and in some schools of others, the fish swim with their heads side by side; in other species (*e.g.,* herring) the head of each fish lies next to the middle of its neighbour's body. The schools may spread out or become very tight, depending on the occasion.

The adaptive value of schooling

The primary advantage of the schooling habit seems to lie in the safety of the individual fish. Sardines react to attacks by predators by swimming closer together and milling around in tight, compact balls; herring form a close school with any approach of danger. The reaction of anchovies to predators is even more intense; a school that may be spread over several hundred metres contracts at the approach of a predator to a moving, writhing sphere of thousands of fishes only a few metres across. In such a situation the predator cannot concentrate on a single individual and may be frustrated in its attempt to catch any fish. The adaptive value of schooling behaviour is poorly understood, but several logical explanations have been advanced. Schooling evidently provides a better chance for small fish to survive many environmental hazards than if they live solitarily. The instinctive tendency of the tiny larva to associate, even though hatched from scattered eggs, ensures the formation of the school, with its protection from predation. Certain hydrodynamic interactions between members of the school are thought to facilitate feeding movements; and the aggregation of so many fish simplifies the finding of mates.

Although anchovy schools progress steadily through the water, they do not seem to have any leader or leader groups. Observers from the air have noted that

> fish travelling in the vanguard often drop back and are replaced by others from the flanks and this is repeated in due course. When the school changes course, the fish from the flank find themselves on the leading edge and the previous leading edge becomes a flank. These manoeuvres are carried out with such precision that one has the impression of watching a single creature moving through the water.

The behaviour of the school is determined most probably by the order of feeding. If a school were to swim straight forward, the fish in front would capture most of the food organisms, and those in the rear would starve. Instead, the leading individuals turn back to either flank and, step by step, return to the rear of the school; in this way, each fish gets its turn to feed.

The depth at which the schools swim depends on the movements of plankton, light intensity, temperature, and the maturation cycle of gonads (*i.e.,* whether or not the fish are in breeding condition). There are diurnal vertical movements of schools, related mainly to the corresponding movements of plankton. Most clupeiform schools are believed to stay near the bottom or in deep water during the day and to move toward the surface during the night. Herring often make a vertical migration from a depth of 300 to 400 metres (roughly 1,000 to 1,300 feet) in the day toward the surface water at night; they therefore move from deep cold waters of about 3° C (37° F) to somewhat warmer surface waters of 5° to 7° C (41° to 45° F). On moonless nights clupeid schools can be concentrated on the surface by beams of strong light, a behavioral pattern often exploited by fishermen.

FORM AND FUNCTION

Distinctive differences in fin position

Distinguishing characteristics. The main differences evident among the various clupeiform groups lie in the positions and sizes of the various fins. If a herring (*Clupetta*), pilchard (*Sardinops*), and sprat (*Sprattus*) are held, each by the leading edge of its dorsal fin, the herring hangs approximately horizontally, because the fin is at the centre of the back; the pilchard hangs with its tail lower, the fin being nearer the head; and the sprat drops its nose, because the fin is nearer the tail. The differences of fin position are not pronounced in the larvae, which have a characteristically elongated form with the dorsal, pelvic, and anal fins located far back. The forward part of the body forms an extremely elongated wormlike feature, and, most characteristic, the dorsal fin is never above the pelvic fins as it is in adults, but is well back, usually somewhere between the pelvic and anal fins; in larval anchovies it is even above the anal fin. During the larval transformation the elongated anterior part of the body becomes progressively shorter, as the fins shift forward by a complicated morphological process. The dorsal fin is shifted forward above the lateral body muscles (myomeres); the pelvic fins move backward to their adult position; and the anal fin moves forward simultaneously. In adults of the families Denticipitidae and Chirocentridae, the dorsal fin stays above the anal fin, far back on the body; in the Engraulidae it usually stops a little farther back than the pelvic fins; and in the Clupeidae it generally reaches a position directly above the pelvic fins. As a rule, however, even within families and genera the relative positions of the dorsal, anal, and pelvic fins are somewhat variable and are often used in classification. The position of the dorsal fin becomes stable at the time the larvae transform into juveniles. The positions of the anal and pelvic fins, however, often change later in life, probably because of the swelling of the body cavity with gonad development.

With only a few exceptions, fishes with more forwardly positioned dorsal fins have fewer rays in their anal fin but more rays in the dorsal. The lateral line canals on the head are most developed in fishes with the dorsal fin located anteriorly. The lateral line system serves as an orientation device. As it is sensitive to disturbances in the surrounding water, it is most important in fishes that school densely. Not surprisingly, the species with the most progressively developed morphological features (*i.e.,* the greatest changes from the "primitive" condition of the larval stage), such as the anteriorly located dorsal fin, a smaller number of rays in the anal fin, and a strong lateral-line system on the head, are the best swimmers and undertake the longest migrations.

Relative numbers of denticles and teeth

The development of denticles (toothlike skin projections) and teeth represents another specialization of evolutionary importance. The most primitive clupeiform fishes have an enormous number of dermal denticles (on the head and in the mouth), which have been replaced in evolutionally more advanced forms by teeth, which are larger and fewer in number. In *Denticeps,* for example, the whole head and part of the body are covered by numerous small dermal denticles. Different species of the Clupeidae have small denticles or teeth limited to the bones of the mouth cavity, and anchovies have rows of tiny teeth in the jaws. Finally, *Chirocentrus* has straight sharp teeth on the upper jaw, the tongue, and in a few other places in the mouth, and has large "canine" teeth on the lower jaw.

The value of the ventral keel

The ventral part of the body in the majority of clupeiform fishes forms a keel, the function of which is widely considered to be an adaptation for removing the sharp shadow that would be created below the central part of the body by top lighting, were the fish cylindrical. Prevention of such a shadow is important to an open-water fish often living close to the surface and unprotected from all sides. Seen from below, the keel and the glossy silver

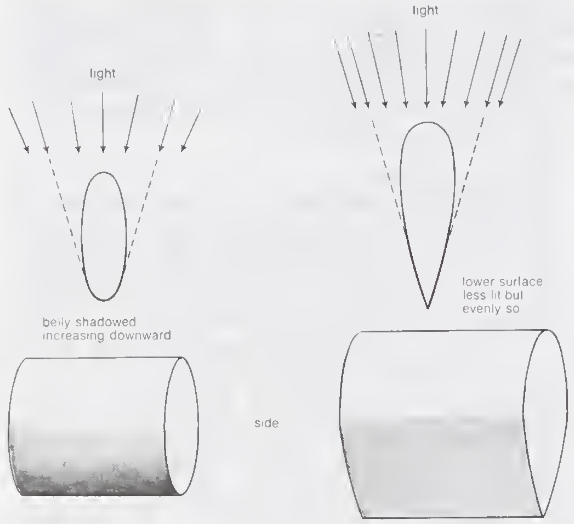

Figure 21: Value of the keeled belly in surface-swimming fishes (see text).

sides of the body cause the fish to disappear in the mirror-like reflection of the water surface. Viewed from above, the fish is protected by the dark cryptic colouring of the dorsal part, which simulates the colour of the deep water. The predator who encounters and sees the whole school is also deceived by the resemblance of the tight school to a larger organism. Against man's nets and electronic devices, however, such coloration and schooling behaviour afford little protection.

Physiology. The movement of anadromous clupeiforms from the salt ocean into freshwater rivers and lakes requires special physiological adaptations to regulate the blood's osmotic pressure (basically, the pressure of a water solution of salts exerted in either direction against a semipermeable membrane caused by differences between the concentrations of dissolved salts within the body and those outside, in the sea). When a fish enters water of salinity lower than seawater, slight increases in osmotic pressure cause the kidneys to excrete larger amounts of water. The conversion from saltwater to freshwater physiology requires some time, however, so the fish usually remains in brackish waters to avoid a sudden physiological shock. During the periods when anadromous fishes are migrating into or out of freshwater, they form large aggregations in estuaries, awaiting the changeover in their osmotic regulating systems.

CLASSIFICATION

Distinguishing taxonomic features. Three main character complexes have recently been recognized and accepted as distinguishing the clupeiform fishes: (1) the presence of an internal connection between the swim bladder and the inner ear, usually forming two large vesicles (cavities) within the skull bones; (2) certain peculiarities of the skull, involving the relation of the lateral line canals to each other and to the ear; (3) certain complex features in the caudal (tail) fin skeleton.

Annotated classification. A recent and widely accepted classification of the order Clupeiformes by P.H. Greenwood *et al.* is presented below. These authors consider the Clupeiformes as the only order in the superorder Clupeomorpha, which formerly included other major fish groups (see above).

ORDER CLUPEIFORMES

Silvery, laterally compressed fishes; mainly marine, but many anadromous or wholly freshwater; mostly pelagic and schooling fishes. Lateral-line canal on head usually extending over operculum (gill cover). About 400 living species.

Suborder Denticipitoidei

Caudal skeleton of extremely primitive type; small arches present on 2 centra (bodies of vertebrae) to carry the first 3 hypural bones (fused spines of the vertebrae) of the tail fin. One family.

Family Denticipitidae

The most primitive living clupeiform. Numerous dermal denticles present on head, on the dorsal part of the secondary pectoral girdle, and on the scales around the anterior end of the lateral line. Lateral line completely developed on the trunk. A single living species, *Denticeps clupeoides*, in fast-running clear water in medium-sized streams of West African Nigeria; and a single fossil species, *Palaeodenticeps tanganikae*, from the Tertiary lacustrine sediments in East African Tanzania.

Suborder Clupeoidei

Characteristic caudal skeleton: the second hypural bone lacks any connection with the urostyle (tail support) and is separated from it by a distinct gap. Lateral line pores completely lacking on trunk. Keeled scutes (projecting scales) usually present along the ventral midline of the abdomen.

Family Clupeidae (herrings, sardines, pilchards, shads, menhadens, and allies)

Teeth usually absent in mouth or very weakly developed; minute in jaw. Keel scales well developed, except in round herrings (subfamily Dussumieriinae), in which they are absent, and the ventral part of body rounded. About 50 genera and 190 species, virtually worldwide in marine waters and in many bodies of freshwater.

Family Engraulidae (anchovies)

Mostly smaller fishes than clupeids, with the snout projecting beyond the very wide mouth. Upper and lower jaws usually armed with rows of minute teeth that sometimes become larger in the posterior end of the jaws. About 200 species; primarily marine with a few anadromous; found in very large schools.

Family Chirocentridae (wolf herrings)

Body laterally compressed and elongated, with sharp, keeled ventral margin; scales small. Lower jaw strongly projecting; large fanglike teeth in both jaws. Two species, *Chirocentrus dorab* and *C. nudus;* widely but sparsely distributed in the Sea of Japan, the Pacific Ocean off Australia and in Melanesia, the Red Sea, and along the east coast of Africa. Used for food in some areas but not very palatable. Larger than other clupeiforms, reaching at least 3.6 metres (12 feet) in length.

Critical appraisal. Until the revision of the bony fishes by Greenwood and his colleagues in 1966, the most widely accepted classifications were those by an American, C.T. Regan, in 1929, a Soviet ichthyologist, L.S. Berg, in 1940, and two from France, L. Bertin and Camille Arambourg, in 1958. The three earlier systems differ widely from one another in the scope of the order Clupeiformes, in the subdivisions of the order, and in the order of families, but they have in common the inclusion of many more groups than were considered related to the clupeid fishes by Greenwood *et al.* The earlier classifications grouped together in one order, Clupeiformes or Isopondyli, a large number of fishes characterized by having soft, as opposed to spiny, fin rays.

Greenwood *et al.* postulated, on the basis of a number of other features in both modern and fossil fishes, that this similarity is overridden by more fundamental differences that indicate a long history of phyletic separation. These authors separated the families Denticipitidae, Clupeidae, Engraulidae, and Chirocentridae in a distinct superorder Clupeomorpha, placed in Division I, one of the three subgroups of the bony fishes. The bony tongues, mormyrs and relatives, treated by Bertin and Arambourg as suborders of the Clupeiformes, were placed by Greenwood *et al.* in the superorder Osteoglossomorpha, sole group in their Division II. The remaining fishes formerly included in the Clupeiformes, consisting mainly of the salmons, trouts, pikes, and a number of deepsea forms, were placed in a large order Salmoniformes, part of Division III. (E.K.B.)

Bony tongues, freshwater butterfly fishes, and allies (Osteoglossomorpha)

The superorder Osteoglossomorpha is a group of morphologically and biologically diverse primitive fishes primarily found in freshwaters; a few species enter slightly brackish water. Their relationship with other teleosts (*i.e.*, advanced bony fishes) is obscure; they probably were an early offshoot from the basal teleost stock. Osteoglossomorpha comprises six extant families and about 150 species. Although the group is of little importance to man, in parts of Africa, Asia, and South America certain osteoglossomorph species are sometimes sought commercially as food fishes.

Except for one North American family (Hiodontidae), the Osteoglossomorpha are tropical fishes. The families Mormyridae (elephant-snout fishes, mormyrs), Gymnarchidae, and Pantodontidae (butterfly fishes) are confined to Africa; the Notopteridae (featherbacks) occur in Africa, Southeast Asia, and India. The distribution of the Osteoglossidae (*e.g.*, pirarucu, arawana) in Africa, South America, and Australasia (believed by many authorities to have once been joined as a single landmass called Gondwana) is of particular zoogeographical interest.

The pirarucu (*Arapaima*) of the Amazon, one of the world's largest freshwater fishes, attains a length of three metres (about 10 feet); other osteoglossomorphs—for example, certain mormyrids—are only a few centimetres long.

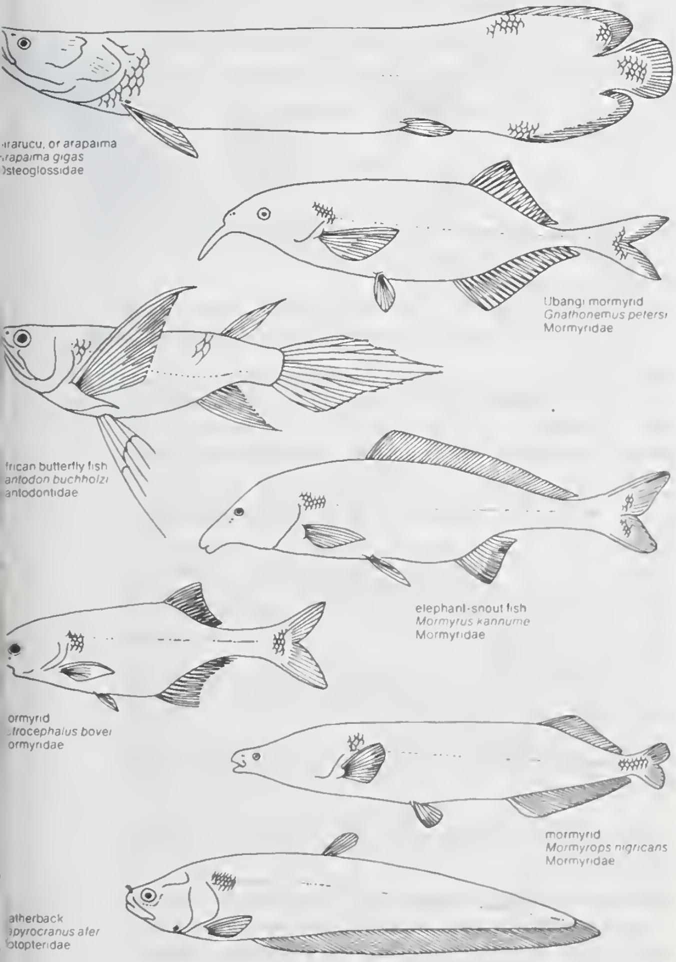

Figure 22: Representative osteoglossomorphic fishes.

NATURAL HISTORY

Life cycle and reproduction. A variety of breeding habits have evolved among the Osteoglossomorpha. In some species there is considerable care of the young by the parents. Although no species is known to undertake extensive breeding migrations, many leave the usual habitat and move into floodplains or streams at breeding time.

The breeding biology of the Mormyridae has been little studied; it does not seem likely, however, that they prepare spawning nests or exercise much parental care. In contrast, *Gymnarchus niloticus* (Gymnarchidae) prepares a large floating nest from the matted stems of swamp grasses, biting off the stems and fashioning them into a trough-shaped structure with an internal length of about 50 centimetres (20 inches). Spawning takes place in the nest, and one or both parents guard the developing young for approximately 18 days.

Nests are not made by notopterioids, but they do establish a breeding territory. Both *Hiodon* species (goldeye and mooneye) spawn in the spring. Eggs are laid on gravel or rocks in shallow, quiet water, which the adults reach after a short migration. The young of the goldeye (*H. alosoides*) remain there until late summer before migrating downstream. In *Notopterus chitala* (Notopteridae), one parent, probably the male, clears an area of the bottom near some submerged object (*e.g.*, rock, plant stem, or piling) on which the eggs are later laid in circular bands; the male guards the developing embryos.

Care of the young

Members of the Osteoglossidae care for their young in a variety of ways. The South American *Osteoglossum bicirrhosum* and its Indo-Australian relatives *Scleropages leichardti* and *S. formosus* carry the eggs and young in the mouth of one parent; little else is known of their breeding habits. The African *Heterotis niloticus* prepares a crude nest from grasses in newly flooded swamp plains. The male guards the young and leads them from the nest on feeding excursions. Both sexes of *Arapaima gigas* of South America dig a spawning pit and guard the developing embryos, which hatch and leave the pit after about seven days; care is provided by the male, around whose head the young congregate. The dark colour of the male's head seems to provide the chief stimulus for shoal orientation; *i.e.*, forming groups or schools. Apparently there is also a gustatory (*i.e.*, taste) or olfactory (*i.e.*, smell) stimulus in a secretion from glands on the male's head. Parent–young groups persist for two to three months; if the male dies, the young join other shoals.

Spawnings in aquaria suggest that *Pantodon* (Pantodontidae), the African butterfly fish, produces floating eggs and provides minimal parental care. A complicated courtship in this species has also been observed.

Electrical organs

Behaviour and ecology. Mormyridae and Gymnarchidae are of particular interest because they have electrical organs. Electrical discharges from these organs are in the form of pulses, the frequency and nature of which are different in each species. In nature, electrical discharges ranging from an output of about 120 to 300 pulses per second have been recorded.

The flow pattern of the electric field around the fish is distorted by the different conductivity of objects that pass into it. These variations are detected by modified nerve cells (mormyromasts) in the skin. The greatly varying conductivity differences among animals and inorganic objects make it possible for mormyrids to use their electrical organs to distinguish between prey, predators, and obstacles in the turbid water they often inhabit. Discharges from the organs also serve as signals to other mormyrids.

Some mormyriforms tend to swim with little body movement, using instead the dorsal fins for propulsion. This unusual swimming method is probably associated with the use of electric organs in navigation and detection; *Gymnarchus*, for example, swims with its body held straight, propulsion being provided by undulations of the dorsal, or back, fin. Since electrical organs lie near the tail, side-to-side movements of the tail end (as in normal swimming movement) would constantly change their position relative to that of the receptor organs, which are in the head area.

Rigid-bodied swimming like that of the mormyriforms also occurs in the featherbacks (Notopteridae), which use the long anal fin for propulsion. There is no electrical organ in the notopterids, however; the rigid body of these fishes may be correlated with the long, gas-filled swim bladder that extends into the tail end of the body.

All other osteoglossomorphs swim by using the body musculature and caudal (tail) fin in the usual manner. The little African butterfly fish (*Pantodon*) has greatly expanded winglike pectoral fins (behind the gills), which are used for short flights in the air, either to escape predators or to catch insects. *Pantodon* habitually swims or drifts just below the water surface. It leaps from the water by means of a powerful thrust of the pectorals, sending the fish 30 centimetres (about a foot) or more vertically out of the water. Short horizontal flights of about one metre (40 inches) are also executed.

Some species of Osteoglossidae (*Heterotis, Arapaima*), the related Pantodontidae, certain Notopteridae (*Notopterus, Papyrocranus, Xenomystus*), and the Gymnarchidae are able to breathe air at the surface; thus they can live in areas where the water is deoxygenated.

The notopterid *Xenomystus* produces sounds that are

The swim bladder, noise-making, and hearing

used as warnings and in courtship. Swim-bladder structure in other Notopteridae suggests that they are also capable of emitting sounds. In all Notopteroidei (including the Hiodontidae) the swim bladder is closely connected with the inner ear, a condition that may be an aid to hearing. Except for the osteoglossid *Heterotis*, all the osteoglossomorphs are carnivorous, the smaller species (and young of all species) feeding on insects and other invertebrates, the larger species on fish. *Heterotis* feeds on microscopic plants and animals filtered from the water.

Osteoglossomorph fishes occupy a diversity of habitats in rivers and lakes, often in turbid waters or in regions with dense aquatic vegetation. A few species seem to require open waters, and some Notopteridae can tolerate slightly brackish water.

FORM AND FUNCTION

All living Osteoglossomorpha have strongly toothed jaws. The jaws are not protrusible, but in piscivorous (*i.e.*, fish-eating) species the gape is sometimes considerable. The Mormyridae show a great variety of head shape and mouth form. Many insectivorous (*i.e.*, insect-eating) species have a small mouth at the tip of a long, curved, tubular snout; they feed by probing among rocks or in soft mud. Piscivores have larger mouths and short snouts.

The mouth is large in all Osteoglossidae, which, like the Notopteridae and Hiodontidae, have a more typical head shape than do the Mormyridae. *Heterotis* has complex spiralled structures lying above the gill arches on each side of the head and opening into the pharynx. Food particles, drawn into the pharynx with the respiratory current, are filtered out and concentrated in these organs.

In all Mormyridae and in the Gymnarchidae, a short length of body musculature toward the tail is modified to form the electric organ. These muscles have lost the ability to contract and have undergone considerable cellular reorganization, from slender fibres of ordinary muscle into thin, flat, electroplates, the structures in which electricity is produced. There are about 300 to 400 electroplates in mormyrid electric organs, and 600 to 800 in those of *Gymnarchus*. The brain, particularly the cerebellum, of mormyriforms is the largest known among fish; the cerebellum is associated with the electroreceptor organs (mormyromasts) in the skin.

A well-developed swim bladder is present in all Osteoglossomorpha. In the air-breathing osteoglossids, pantodontids, and gymnarchids, it is highly vascularized (*i.e.*, has many blood vessels), and its inner surface is honeycombed with tiny pits.

Paired extensions in the Notopteridae and Hiodontidae connect the swim bladder with the auditory region of the skull. In the African genus *Papyrocranus*, diverticula (outpocketings) of the swim bladder actually penetrate the skull, a condition that probably improves hearing. Posteriorly the swim bladder in notopterids extends beyond the abdominal cavity and runs back on either side of the vertebral column. In the early embryos of Mormyridae and Gymnarchidae, a pair of thin tubes extends forward from the swim bladder into the skull; later the tubes atrophy, leaving an isolated vesicle—a blister, or balloon-like structure—within the skull surrounded by the semicircular canals of each ear.

The inner ear shows various modifications; in notopterids, gymnarchids, and mormyrids, the upper portion (for balance) is completely separated from the lower part (for hearing).

In the Mormyridae and Pantodontidae, the anal fin shows considerable sexual dimorphism in shape—*i.e.*, the anal fin of males differs from that of females. These differences may be related to spawning activity.

CLASSIFICATION

Distinguishing taxonomic features. Classification in the superorder Osteoglossomorpha is based largely on skeletal characters, in particular the caudal-fin skeleton; the bones around the eye; and the gill arches and their associated dentition. Details of the inner ear and swim-bladder anatomy are also of importance.

Annotated classification. The classification used here is based on that of P.H. Greenwood, D.E. Rosen, S.H. Weitzman, and G.S. Myers (1966), with subsequent research by Greenwood (1970) and G.J. Nelson (1968, 1969). Groups indicated by a dagger (†) are extinct and known only from fossils.

SUPERORDER OSTEOGLOSSOMORPHA
Primitive; well-developed teeth on tongue, skull base, and bones of the mouth cavity; caudal fin skeleton of characteristic form. Lower Cretaceous to Recent.

Order Osteoglossiformes
Osteoglossomorph fishes without electric organs.

Suborder Osteoglossoidei
Swim bladder not connected with skull; semicircular canals and lower part of inner ear connected.

Family Osteoglossidae. Fishes of diverse body form; pectoral fins not greatly enlarged, pelvic fins abdominal in position. Genera: *Arapaima* (1 species) and *Osteoglossum* (2 species), South America; *Scleropages* (2 species), Australia, New Guinea, Borneo, Sumatra, Malaysia, Thailand; *Heterotis* (1 species), Africa. Fossils from Eocene of North America and Tertiary of Australia (*Phareodus*); Eocene of Sumatra and Tertiary of India (*Musperia*).

†*Family Singididae.* Extinct. Apparently toothless; monotypic genus (*Singida*) from Paleocene of Tanzania (East Africa).

Family Pantodontidae. Greatly expanded winglike pectoral fins; pelvic fins thoracic. A monotypic genus, *Pantodon buchholzi*, from Africa. No fossil record.

Suborder Notopteroidei
Swim-bladder connected with the skull; semicircular canals separate from lower part of ear, or, if connected, utriculus greatly enlarged.

†*Family Lycopteridae.* Extinct. Lower Cretaceous of northeast Asia; small freshwater fishes resembling the Hiodontidae. 4 genera (6 species).

Family Notopteridae. Long anal fin confluent with reduced caudal; dorsal fin small or absent. Genera: *Papyrocranus* (1 species) and *Xenomystus* (1 species) in Africa, *Notopterus* (4 species) in Asia and Indonesia. Fossil *Notopterus* from Eocene of Sumatra.

Family Hiodontidae (goldeye and mooneye). Probably the most primitive living osteoglossomorphs. One genus, *Hiodon*, confined to North America. Fossil from Eocene of British Columbia (*Eohiodon rosei*).

Order Mormyriformes
With electrical organs; very diverse head shape and mouth form. Confined to Africa; fossils from Pliocene of Egypt; 2 families, about 130 species.

Family Mormyridae (mormyrs and elephant-snout fishes). Anal, caudal, and dorsal fins present; several genera; about 130 species.

Family Gymnarchidae. No anal fin; long dorsal confluent with reduced caudal fin. One genus and species, *Gymnarchus niloticus*.

Critical appraisal. Taxonomic problems of the osteoglossomorphs concern intragroup relationships, particularly whether the Mormyriformes are more closely related to the Osteoglossoidei or to the Notopteroidei. Some authorities relate the Mormyriformes with the Notopteroidei; others suggest closer affinity with the osteoglossoids and propose that one order, rather than two, should be recognized. The superorder as a whole presents problems of relationship with the other teleostean lineages. Certain fossil groups—*e.g.*, the Eocene genus *Brychaetus* and the Mesozoic families Plethodontidae and Ichthyodectidae—may be osteoglossomorphs, but their relationship with the living groups is still obscure. *Brychaetus* can probably be classified in the Osteoglossiformes, but it may represent a distinct suborder. (P.H.G.)

Salmons, trouts, whitefishes, and allies (Salmoniformes)

The order Salmoniformes is a diverse and complex group of fishes. The order consists of about 1,000 species in the fresh waters and in the oceans of the world. Included are the familiar trout, salmon, and pike, as well as most of the bizarre forms of fishes inhabiting the middepths of the oceans.

The framework of the order Salmoniformes in the dis-

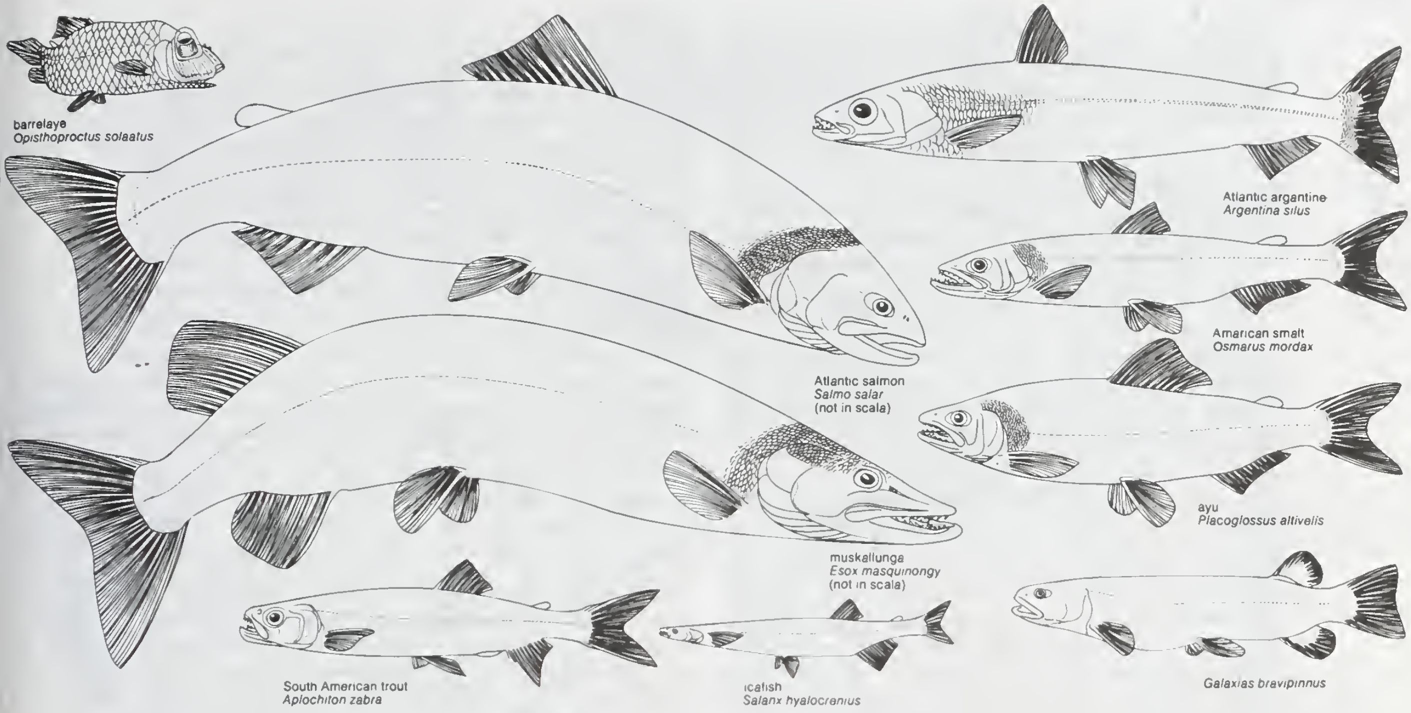

Figure 23: Body plans of representative salmoniform fishes.

cussion below should not be considered as a definitive taxonomic category but rather as an assemblage of diverse fishes possessing several primitive anatomical features representative of an early stage in the evolution of modern bony fishes (teleostean fishes).

GENERAL FEATURES

Evolutionary importance of the order. The significance of the order Salmoniformes as presently classified—a major departure from early schemes of fish classification—is in the evolutionary position of the group; the Salmoniformes are now considered a basal stock in the mainstream of modern bony-fish evolution. The present classification implies that the ancestors of salmoniform fishes developed several evolutionary trends in the Late Mesozoic Era, about 100,000,000 years ago, providing the necessary source of evolutionary raw material to initiate several successful evolutionary lineages, ultimately leading to most of the modern bony fishes.

Divisions of the order

The order Salmoniformes, as treated in this article, is based on the combined work of a British ichthyologist and several American ichthyologists, who have divided the order into eight suborders and 37 families. Constructed in this way, the order Salmoniformes brings together a variety of extremely diverse groups. Several major alterations have recently been proposed for the classification of salmoniform fishes; thus the classification used in this article is provisional and may be subject to extensive changes when more precise information is available. The order Salmoniformes can be considered more as an evolutionary grade in the phylogeny of teleostean fishes than a well-defined taxonomic category. No single character or group of characters can distinguish all salmoniform fishes from all other fishes.

Reasons for interest in the order. The trouts, salmons, chars, whitefishes, and graylings of the family Salmonidae are the most widely known and intensively studied family of fishes. Their famed sporting qualities and excellent taste ensure their economic importance. At the other extreme, some deep-sea families of salmoniform fishes are known only to a few ichthyologists, and often only on the basis of a few imperfectly preserved specimens. The bulk of salmoniform species are fishes of the middepths (mesopelagic and bathypelagic zones) of the open oceans. The deep-sea salmoniforms have evolved unusual body forms and structures—such as luminous organs, telescopic eyes, complex appendages, and enormous and well-developed jaws and teeth—to cope with existence in the twilight and dark zones of the ocean and are of great interest in the study of evolutionary and developmental biology. Some of the anatomical structures evolved by the deep-sea salmoniforms are among the most striking and strange ones found in the animal kingdom.

Size range. The largest of the salmoniform fishes are members of the family Salmonidae and include the Pacific king salmon (*Onchorhynchus tshawytscha*) and the Danube and Siberian huchen (*Hucho hucho*), both of which are known to attain a weight of 50 kilograms (110 pounds) or more. The North American muskellunge (*Esox masquinongy*), a member of the pike family, also approaches this size. The majority of the salmoniform species, however, are small. Most of the deep-sea species do not exceed 150 millimetres (six inches) in length, and many at maturity are no more than 25 to 50 millimetres (one to two inches) long. The largest of the marine salmoniforms is one of the lancet fishes (family Alepisauridae); this species may reach a maximum length of 2.1 metres (about 7 feet). The lancet fish has an elongated body with tremendously enlarged, dagger-like teeth, a fragile sail-like dorsal fin, and a soft, flaccid body. Occasionally a lancet fish migrates from the ocean depths to the surface and may be caught by a fisherman or found washed up on a beach. Lancet fishes, like other deep-sea salmoniforms, are so highly modified that the relationships to trout and salmon are not obvious. A basic salmoniform feature, however—the small, fleshy adipose (fatty) fin that is situated between the dorsal fin and the tail—is found on both trouts and lancet fishes and has been inherited from a very ancient, but common, ancestor.

Most salmoniform species, including the smaller forms, are predacious fishes. Many peculiar modifications have been evolved by the small species of marine salmoniforms to allow them to capture and consume prey sometimes as large as themselves. Some of these lilliputian monsters appear to be mostly head and jaws, all out of proportion to the soft, gelatin-like body. The lack of a neck in fishes limits the mobility of the head and jaws; remarkable adaptations increase the flexibility of the head and allow a great enlargement of the mouth opening to engulf prey quickly. Several deep-sea salmoniforms lack bone on the anterior portion of the vertebral column, increasing the flexibility of the head and jaws.

Distribution and abundance. Salmoniform fishes are found in fresh water on all continents and in all of the oceans of the world. Various representatives of the trout, pike, and smelt families are indigenous to the cooler fresh waters of the Northern Hemisphere. Species of the family Salmonidae inhabit the colder waters of North America, from tributaries of the Arctic Ocean to tributaries of the Gulf of California in northwestern Mexico; in Europe and Asia, a comparable distribution is found, from the Arctic Ocean to the Atlas Mountains in North Africa and to the island of Taiwan. One member of the family, the Arctic char (*Salvelinus alpinus*), is the most northerly occurring of any freshwater fish. The development of an anadromous life cycle—spawning in fresh water but migrating to the sea for feeding and maturation—has allowed species of trout and salmon to extend their range greatly, particularly into fresh waters of glaciated regions after the glaciers recede and waters become inhabitable. The use of marine invasion routes allows a rapid expansion in the distribution of a species into new areas, often inaccessible to other species completely restricted to a freshwater life cycle. Species of the family Salmonidae are clearly the dominant fishes of the recently glaciated fresh waters of the Northern Hemisphere.

The anadromous life cycle

The pike and its allies (family Esocidae) have a distribution somewhat similar to the Salmonidae; however, their range extends neither so far north nor so far south. The pikes are completely restricted to fresh water throughout their life cycle; however, the distribution of the northern pike (*Esox lucius*) in Europe, Asia, and North America is one of the broadest distributional patterns of any fish species. Such a distribution must have been achieved when direct freshwater connections existed between the present major drainage basins and between Asia and North America. The smelts of the family Osmeridae are small fishes of Europe, Asia, and North America. Some smelts are permanent freshwater inhabitants, but the distribution of freshwater smelts is associated with relatively recent geological events; most smelts are anadromous or marine. No smelt species has penetrated far enough inland to establish a broad distribution in fresh water comparable to that of the salmonid fishes. The other salmoniform fishes with anadromous and freshwater species in the Northern Hemisphere are members of the Far Eastern families Plecoglossidae and Salangidae. In the Southern Hemisphere, salmoniform fishes that are ecologically similar to the trouts and smelts are encountered in the fresh waters of southern Africa, southern South America, Australia, New Zealand, and Tasmania. These fishes are classified in the families Galaxiidae, Retropinnidae, Aplochitonidae, and Prototroctidae (of the suborder Galaxioidei). The galaxioid fishes are typically small (measuring only 100 to 300 millimetres [four to 12 inches]) marine and freshwater fishes. The family Galaxiidae contains the most species (about 35) and has the broadest distribution—in Africa, South America, Australia, New Zealand, and Tasmania. The smeltlike fishes of the family Retropinnidae comprise about six species native to Australia, New Zealand, and Tasmania. The family Aplochitonidae consists of three species in southern South America and a larva-like (neotenic) species in Tasmania. The Prototroctidae has two, troutlike species in Australia and New Zealand. Various species of Salmonidae, particularly the North American rainbow trout (*Salmo gairdneri*) and the European brown trout (*S. trutta*), have been widely introduced and successfully established in suitable waters in Africa, South America, Australia and New Zealand. When introduced into lakes with abundant food fishes but previously lacking large predator fishes, the introduced trout flourish, growing rapidly to a large size. In certain lakes in Australia and New Zealand, famed for their trophy-sized trout, the trout feed avidly on their distant relatives, species of the Retropinnidae and Galaxiidae.

The remaining 25 or more families of Salmoniformes, with about 800 species, are entirely marine, typically mid-depth and deep-sea fishes. Representatives are found in all oceans and all depths, but in temperate and tropical waters major concentrations occur at depths of 200 to 2,000 metres (about 650 to 6,500 feet). The tremendous abundance attained by some populations of these marine salmoniforms has become evident only with the advent of modern sonar equipment, which has detected aggregations many square kilometres in extent.

IMPORTANCE

The economic significance of the trouts and salmons both as sporting fishes and as commercial products is well-known. Governments invest heavily to maintain and increase the production of trout and salmon; hundreds of millions of trout and salmon are hatched, reared, and stocked each year for sport and commerce. In fact, a large private industry has developed—particularly in Denmark, Japan, and the United States—to supply trout to markets and restaurants. With the problems of increased human population and the demands made on rivers by industry and agriculture, the challenge of perpetuating and increasing the abundance of salmon and trout has become a serious one for fisheries scientists.

The demand for trout as a sport fish far exceeds the supply in heavily populated regions. This situation, particularly in the United States, has resulted in a massive program by state and federal agencies to raise trout to acceptable size and to stock them in heavily fished waters. Such an artificial abundance, however, is a poor substitute for natural trout fishing.

National programs assisting sport fishing

Except for the pikes, the remaining freshwater salmoniforms are too small or too rare to be significant sport fish, but most are considered excellent food fish. The oceanic salmoniforms have little direct importance to man; because of their tremendous abundance, however, they form a vital link in the food chain of the oceans, providing forage for valuable predator species such as the tuna. Many of the deep-sea salmoniforms undertake daily vertical migrations, rising toward the surface layer of the ocean at night for feeding. This vertical migration exposes them to predation by larger fishes and functions in the recycling of energy in the ocean by elevating energy accumulated in the lower depths (in the bodies of the small salmoniforms) and making it available to large predators in the upper zones.

NATURAL HISTORY

Life cycle and reproduction. Virtually every type of life cycle and mode of reproduction known for fishes is exhibited by some salmoniform fishes. These life cycles range from passage of the entire life-span in the confines of a small pond or stream to migrations encompassing thousands of kilometres from a stream to the ocean and back to the stream. Some species have a direct development stage from the egg, hatching as miniature adults, ready to fend for themselves. Most deep-sea marine species have larval stages, drastically different from the adult. Some larvae have eyes attached to long stalks from the head. Most salmoniform species consist of males and females, but several deep-sea groups are hermaphrodites, a single individual having functional testes and ovaries. Evidently, in the darkness of the ocean depths, it is advantageous for an individual to function both as male and female.

The life cycles of salmons and trouts have been intensively studied because of the economic importance of salmonid fishes. Factual information the life cycle and reproduction is used to settle disputes between nations regarding the origin of salmon caught in the open ocean and for the intelligent management of the resource.

The life cycle and reproduction of the deep-sea salmoniforms, however, are little known except for interpretations gained from examination of a few specimens and collection of eggs and larvae. Eggs and larvae of many of the marine species have not yet been found.

Among the salmoniform fishes, only the pike family (Esocidae) and the mudminnow family (Umbridae) are completely restricted to fresh water throughout their life cycle. All other families that have freshwater representatives contain some species that enter the marine environment for growth and maturation, returning to fresh water to spawn. One species of the family Galaxiidae has a catadromous life cycle—spawning takes place in a marine environment, and the young migrate to fresh water to mature. All of the oceanic salmoniforms are completely marine throughout their life cycle.

The catadromous life cycle

The families Salmonidae and Osmeridae demonstrate a transition between freshwater and marine life cycles. All species of salmonids spawn in fresh water, but the Pacific

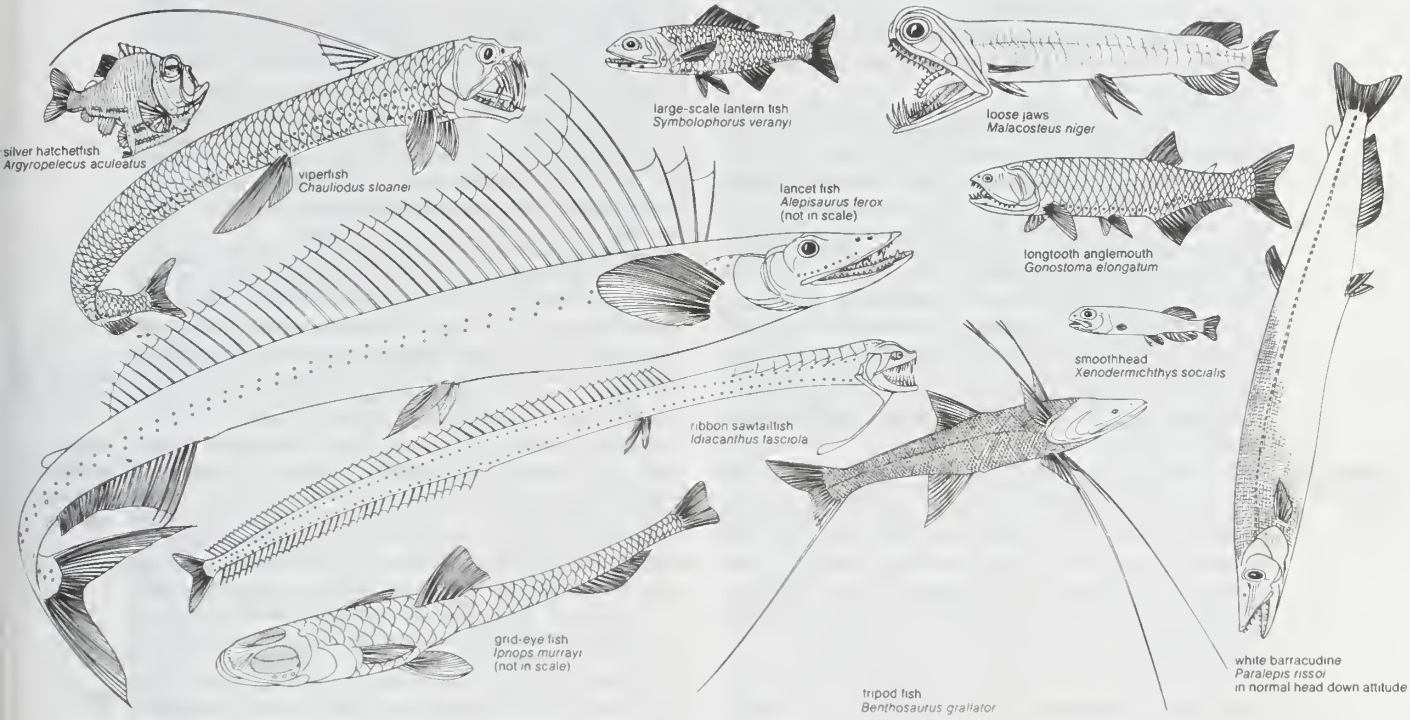

Figure 24: Body plans of representative salmoniform fishes.

pink salmon (*Onchorhynchus gorbuscha*) has reduced the freshwater stage to the spawning migration and incubation of the eggs. As soon as the eggs hatch and the yolk sac is absorbed, the pink salmon fry migrate to sea. Some pink salmon may even spawn in the intertidal zone at the mouths of small streams, virtually eliminating the freshwater stage in the life cycle altogether. Other species of the family Salmonidae, such as the lake char, or lake trout (*Salvelinus namaycush*), the graylings (*Thymallus*), and many of the whitefishes (*Coregonus*), have completely freshwater life cycles. Interestingly, life cycles may differ among closely related species or even between populations of the same species; for example, rainbow trout that go to sea and return as large, silvery individuals are called steelhead trout. A single river system may contain local resident populations of small rainbow trout—maturing, spawning, and completing a life cycle within 100 metres (about 300 feet) of the site of their birth—as well as anadromous steelhead rainbow trout that have returned from the ocean after a two- or three-year journey spanning several thousand kilometres. Evidently the heritable differences that govern the type of life cycle in trouts—anadromous or freshwater—are slight. It has been demonstrated that offspring from anadromous parents can be used to establish populations in completely landlocked environments, and that the progeny of nonanadromous parents may go to sea if given the opportunity.

Reproductive behaviour, the type and size of the eggs laid, and the amount of parental care have been developed in each species by the process of natural selection. In an evolutionary sense, spawning success is ultimately judged by the number of mature adults resulting from any spawning act. If the eggs and larvae are exposed to a harsh and perilous environment, there is a selective advantage for a female to produce fewer but larger eggs and to provide some extra measure of protection for the developing embryos. Cold, swift rivers with sparse food, typically utilized by salmons and trouts for spawning, undoubtedly have been a major selective force in the evolution of large eggs (four to eight millimetres [roughly $^{5}/_{32}$ to $^{5}/_{16}$ inch] in diameter) and of nest-building behaviour in the trouts and salmons.

A large egg with a large yolk to supply food to the developing embryo allows for direct development—that is, the young hatch in an advanced stage, resembling a miniature adult. In more benign environments, such as lakes and the ocean, most salmoniform fishes produce smaller but more numerous eggs, and hatching takes place when the larvae are only partially developed. In many species the larvae are quite unlike the adult form and undergo a rather striking transformation (metamorphosis). Eggs of all freshwater spawning salmoniform fishes are heavier than water (demersal eggs) and develop on or in the bottom of a stream or lake. Marine species typically have pelagic (free drifting) eggs and larvae; the eggs are of neutral buoyancy and thus drift with the currents in the surface layer of the ocean. The eggs and larvae of many deep-sea salmoniforms have not yet been described, and in some species the eggs and larvae may be associated with the ocean bottom.

As far as known, all salmoniform fishes lay eggs and have external fertilization (oviparous fishes). In several of the deep-sea salmoniform families, in which hermaphroditism is common, it is not known if the species are self-fertilizing.

Some of the deep-sea salmoniforms have luminescent organs, one of the functions of which probably is sexual recognition. In the lantern fishes (Myctophoidei), the light organs are arranged in distinctive patterns that distinguish males and females of a species.

Behaviour and locomotion. Only the freshwater salmoniform fishes can be studied in any detail by direct observation. Most of what is known about the deep-sea species is based on preserved specimens, and, for most species, behaviour and locomotion can only be surmised from an examination of the morphology and anatomy.

The generalized body form of trout and salmon is characteristic of active, swift-moving fishes. A trim, fusiform body, powerful caudal (tail) muscles, and a well-developed tail combine to propel the fish against strong currents with a minimum of resistance. These features also give the trout or salmon the ability to leap barrier falls as high as three metres (10 feet) or more.

Adaptations of predators

Predatory fishes that dart out to grasp their prey are exemplified by the pike, in which the dorsal fin is situated posteriorly on the body to act more as a rudder than a keel. The pikelike body form has been evolved independently many times among predatory fishes such as the barracuda (*Sphyraena sphyraena*, of the order Perciformes). Among the deep-sea salmoniforms, however, certain predatory species are sedentary and have only weak swimming ability. Such fish remain immobile until unsuspecting prey ventures close enough to be grasped. Some evidently use a luminous lure to attract their prey.

A peculiar type of locomotion is encountered among the barracudinas (family Paralepididae), marine salmoniforms of the suborder Myctophoidei. The barracudina swims in a vertical plane, darting up and down with the head oriented downward.

The behaviour of a fish toward other members of its species can be highly variable. Often, predator species are territorial and aggressive, whereas plankton-feeding species typically form schools and do not function normally unless they are close to other members of their species. Although behaviour patterns are largely innate and species-specific, striking differences occur between closely related species. Pink salmon fry, on hatching, seek each other and form schools prior to seaward migration. The young of the coho, or silver salmon (*Onchorhynchus kisutch*), however, establish territories and aggressively attack other young cohos that invade their territory. This difference in aggressive behaviour is associated with the longer period of freshwater life and limited food supply experienced by the coho salmon.

Homing by trout and salmon

One fascinating aspect of the behaviour of trout and salmon is their homing instinct—*i.e.*, the ability to return to the stream of their birth after migrating thousands of kilometres in the ocean for one to three years. Homing to the site of birth for reproduction is apparently a rather universal trait among the Salmonidae. Trout, char, and whitefishes in lakes segregate into discrete populations during the spawning season, each at a specific site.

It is now generally accepted that the sense of smell plays the major role in guiding an anadromous trout or salmon to its precise natal stream once it enters a river drainage from the ocean. How it finds the mouth of the river system leading to the natal stream from the open ocean is not yet understood; celestial navigation and detection of fields of gravity by some unknown means have been hypothesized. Several senses besides smell may be used to locate the natal stream. Cutthroat trout (*Salmo clarki*) in Yellowstone Lake, Wyoming, have been found to be able to return to their spawning stream after experimental blocking of the senses of smell and sight.

Homing behaviour has allowed the development of discrete populations among anadromous species of salmon and trout. Different life-history characteristics can be maintained because different populations segregate for spawning, and individuals of a population spawn only with each other, perpetuating hereditary traits. In major river systems such as the Columbia and Fraser in North America, one species may include several distinct races, each having different life cycles; such a situation greatly complicates the management of a species.

Ecology. As with other aspects of the biology of salmoniform fishes, the ecology of species of the family Salmonidae is best known. All species of salmonid fishes evolved in clear, cold water, and they thus require pure, well-oxygenated, cold water; for this reason salmonid fishes are the first species to suffer when water quality is degraded. Other freshwater salmoniforms, although not quite so sensitive to water quality as the salmonid fishes, are also susceptible to the inimical effects of man-induced environmental degradation.

Most salmoniform fishes are predators, feeding on other fish and large invertebrates. The process of evolution, however, works to modify and adapt species for certain ecological specializations in order to exploit a variety of food resources. In the lakes of the Northern Hemisphere, several whitefish species (*Coregonus*) are comparable, ecologically, to the herrings in the ocean. Such whitefishes, which are often called freshwater herrings, cruise the open water of lakes, filtering out minute organisms by straining the water through a fine mesh of gill rakers—minute bony elements attached to the gill arches. The sheefish, or inconnu (*Stenodus leucichthys*), a large, predatory whitefish of the Arctic, demonstrates that evolution for ecological adaptation is occasionally reversible: the adults feed on other fish and have evolved a pikelike body shape and large, powerful jaws, the development of teeth taking precedence over that of the gill rakers; the sheefish is quite unlike the typical whitefish from which it has evolved.

There probably has been strong selection for freshwater salmoniforms to utilize the marine environment for feeding. All groups except the esocoid fishes (pike family and related groups) have species that migrate to the ocean for feeding. This presents a problem of osmotic regulation in waters of different salinities. The physiology of most fishes is fixed for life in fresh water or in the sea, but most of the freshwater salmoniforms are able to live in the sea because they can excrete excess salts through cells in the gills. They also possess well-developed kidneys, which, in the freshwater environment, handle the excess of water that diffuses into their blood via the gills.

Little is known of the ecology of the wholly marine salmoniforms. They may be ecologically grouped by the depths that they inhabit and by their feeding preference. Those found in the twilight zone of the ocean (200–1,000 metres [650–3,300 feet]) consist of plankton feeders and predators. The plankton feeders typically are more active and have a more fully developed and functional swim bladder than is typical of the predatory forms.

Abundance of deep-sea species

Because virtually all primary food production in the oceans takes place in the upper, sunlit layer, the deep-sea fishes live in a food-poor environment. At first, it may seem contradictory that they are able to maintain such numerical abundance; certain features of the biology of the deep-sea salmoniforms, however, allow them to attain great numbers. The body of the typical oceanic salmoniform is feebly developed, appearing to consist of little more than gelatinous material. The skeleton and muscles are reduced, so that little energy is needed to maintain the body. Many of the deep-sea species make nightly migrations to the food-rich surface zone for feeding. The species inhabiting the deepest parts of the ocean must depend on a food supply that filters down from above. This food is concentrated in a narrow bottom layer (the benthic zone), with the result that the benthic species may attain a relatively high abundance.

FORM AND FUNCTION

Features of the generalized salmoniform. *External characteristics.* The tremendous range of structural diversity found in salmoniform fishes has already been mentioned. Comparisons of some of the extreme morphological and physiological modifications with a generalized, standard type can be useful in understanding the evolutionary trends leading to certain specializations. A trout of the genus *Salmo,* such as a rainbow trout or brown trout, can serve as a "standard" for the form and function of salmoniform fishes. The nonspecialized morphology and physiology of a typical trout species allow it to utilize diverse ecological niches during its life. A trout's diet consists of a variety of organisms, and its habitat may vary from small streams, large rivers, or lakes to the ocean. The body and fins are streamlined and symmetrical; the body is covered with small, smooth (cycloid) scales; the fins are formed from soft supporting rays, without spines. A small, fleshy adipose fin is located between the dorsal fin and the tail. The dorsal fin is located midway along the body on the dorsal surface. On the ventral surface, the paired pectoral fins are directly posterior to the head, the paired pelvic (or ventral) fins are directly beneath the dorsal fin, and the single anal fin is positioned beneath the adipose fin. The well-developed tail (caudal fin) connotes a powerful swimming ability. The presence, absence, rearrangement in position, and modifications in size, shape, and function of the various fins are characteristic of the numerous families of Salmoniformes.

Digestive system. The structures associated with feeding and digestion denote the diversity in a trout's diet. The mouth is fairly large with moderate development of nonspecialized teeth on the jaws and on several bones within the mouth. An adult trout can capture and consume a fish about one-quarter its own length without undue difficulty. Feeding on invertebrate organisms, as small as a few millimetres (perhaps $^1/_4$ inch) in length, is facilitated by the gill rakers on the surface of the gill arches; they strain small organisms from a stream of water passing over the gills and funnel them to the esophagus. The well-defined muscular stomach opens by a valve into the intestine. A series of fingerlike appendages opens off of the intestine immediately posterior to the stomach. These appendages, called pyloric ceca, secrete enzymes and provide additional digestive areas to the intestine. Among closely related species of the family Salmonidae, there is a tendency for the more predacious species to have more numerous pyloric ceca. Generalizations relating pyloric cecal development to diet cannot be extended, however, to other fishes. The highly predacious pikes of the genus *Esox* completely lack pyloric ceca, whereas the algae-eating ayu (*Plecoglossus altivelis,* family Plecoglossidae) probably has more numerous ceca than any other fish, up to 400 or more.

Sense organs. Because vision is important in the life of a trout, the eyes are well developed; the retina possesses both rods (for vision in dim light) and cones (for perceiving more acute images and for colour vision). The sense of smell is also highly developed.

The lateral line system

The lateral line nervous system functions as a pressure receptor and a direction finder for objects that move, such as another fish. The lateral line might be considered as a remote sense of touch; it does not, however, function in hearing low-frequency sound waves as was once believed. It has been demonstrated that sound waves are well below the threshold necessary to stimulate the lateral line cells. In trout, the lateral line consists of a series of connected sensory cells (neuromasts) with tiny, hairlike projections. These cells are embedded under the scales along the midline of the body and open to the surface through pores in the scales. An extension of the lateral line system on the head consists of a ramification of sensory canals. In some deep-sea salmoniforms living in the absence of the effects of sunlight, other senses are needed to compensate for vision in perceiving the environment, and the neuromast sensory cells may be exposed on raised papillae, thus increasing their sensitivity.

The swim bladder (or air bladder) has a hydrostatic function, adjusting internal pressure to maintain a weightless condition of neutral buoyancy at various depths. The trouts have a primitive type of swim bladder with a connecting duct from the bladder to the esophagus. The duct is an evolutionary holdover from an ancestor in which the swim bladder was mainly an accessory respiratory organ. Many salmoniform fishes lack the duct, and several deep-sea marine species lack a swim bladder altogether.

Departures from the generalized body plan. From the primitive body plan exemplified by the trouts, it is possible to derive all of the specialized body types of other salmoniform fishes by the elimination of some structures and by the modification, exaggeration, and rearrangement of others.

The pike is an example of a specialized predator whose diet, after the first year of life, consists almost entirely of other fishes. Its success depends on how effectively it captures and consumes other fishes, and its whole morphology and physiology are directed toward this end. A pike has an elongated body with a large head and large, powerful jaws. Its mouth is armed with large, canine-like teeth that can handle large prey. Patches of teeth on the gill arches replace the typical gill rakers. Vision is the primary sense used by pike to detect and capture prey. The visual centre of the brain (optic lobe) is more highly developed than are the centres of smell (olfactory lobes). The eyes have a high proportion of cones to rods in their retinas and are positioned to provide partial binocular vision (*i.e.,* the eyes are aimed in the same direction), sighting down grooves on the snout to aim at moving prey. The body form and position of the fins are specialized for swift, darting movements. The dorsal fin is placed posteriorly, over the anal fin, and, as is typical of other salmoniform fishes with posteriorly oriented dorsal fins, the adipose fin is absent.

The most extraordinary modifications in the basic salmoniform body plan are found among the marine species of the middepths and great depths of the ocean. The more striking adaptations include luminous organs, eyes specialized to function in dim light, feeding adaptations allowing some predatory species to kill and eat a fish as large as themselves, and drastic departures in body shape and fin development.

Luminescent organs

Bioluminescence, the production of chemical light by living organisms, is widespread in nature. Among vertebrate animals, only marine fishes have light organs. Light organs (or photophores) are encountered in many diverse groups of fish. These structures apparently have been evolved independently several times in different groups of fish. It is believed that light organs of fish have evolved from mucous cells of the skin. Salmoniform fishes, particularly species in the suborders Stomiatoidei and Myctophoidei, have developed some elaborate and highly complex light-producing systems. Some structures have lenses, reflectors, and eyelid-like shades. In addition to light cells on the sides of the body, luminous tissue may be found on the head, around the eyes, on fin rays and barbels, and on the ventral surface; in the myctophoid family Paralepididae, an internal duct makes the whole fish glow. The great diversity in the type and position of light organs suggests that they must serve different functions in the groups possessing them. In the family Searsiidae (suborder Alepocephaloidei), a large sac on the shoulder emits a display resembling a shower of sparks when the fish is disturbed. Such a structure probably is a defensive mechanism. Light organs on the head may help in locating food, and those on elongated dorsal fin rays or chin barbels may lure prey. Sexual recognition and territorial behaviour are other suggested functions. Although not all marine salmoniform fishes have light organs, the latter are typically found in species that spend most of their life in the lower twilight and upper dark zones of the ocean. The effects of sunlight essentially disappear at about 700 metres (2,300 feet); the maximum abundance of luminous fishes occurs at about 800 metres (2,600 feet).

Eye adaptations in deep-sea forms

There are some parallels in the development of eyes and light organs in fishes correlated with the depth at which the species lives. Perhaps the most sensitive of all vertebrate eyes is found in fishes inhabiting the dim twilight zone of the ocean; the eyes, specialized to function at very low light intensity, may be greatly enlarged. The retina typically consists entirely of rods with golden pigment to increase sensitivity to blue light of the light spectrum (the last part of the visual light spectrum to be filtered out in water). Another adaptation found in some marine salmoniforms for concentrating weak light is tubular eyes. Fish with tubular eyes appear to be wearing exaggerated goggles. Tubular eyes are aimed in the same direction (binocular vision) and may be directed straight ahead or directly upward. Two sets of retinas are associated with tubular eyes, one on the side of the shaft and one in the normal position at the base. The two sets of retinas function to enlarge the field of vision. A most unusual modification of the eyes is found in the myctophoid genus *Ipnops* (family Ipnopidae), which appears to be eyeless; however, a thin, transparent bony plate on top of the head covers a mass of retinal cells. Evidently such an eye functions to perceive faint luminescence at great depths. Larval stages of a few salmoniforms have eyes extended out from the body on stalks, which are resorbed when the eyes assume a normal position during metamorphosis.

Some grotesque fishes are found among the predatory stomiatoids and myctophoids. The teeth may be developed into tremendously enlarged fangs, which may be likened to daggers, spears, or sabres. The gape of the jaws is sufficiently large to engulf a prey as large as the predator. Stomiatoid predators have a peculiar modification of the anterior vertebral column, which remains unossified, resulting in a flexible jointlike mechanism allowing the head to snap back and enlarge the gape. To allow the swallowing of large prey, the body is soft, distensible, and usually lacks scales; the stomach is highly elastic.

EVOLUTION AND CLASSIFICATION

Evolutionarily important taxonomic characters. Studies of the skeletal system (osteology) and comparative anatomy have produced most of the information used in the classification of salmoniform fishes. At present, however, the taxonomy of Salmoniformes is not well defined because no character or group of characters is exclusive to salmoniform fishes, and little consistent difference in characters occurs among the suborders.

The fishes grouped in Salmoniformes possess a mosaic of primitive characters from which it is possible to derive most of the more advanced orders of teleostean fishes. Both evaluation of the hypothetical evolutionary branching sequences to denote relationships and judgment concerning the primitive or derived (advanced) state of a character are based on an evolutionary principle that a structure lost or highly modified during evolution will never be re-evolved in its original condition; for example, the adipose fin, the mesocoracoid bone of the pectoral skeleton, and teeth on the maxillary bone of the jaw are considered to be primitive salmoniform characters. The absence of these characters represents an advancement; evolutionary lines that have lost these features therefore could not have been ancestral to fishes that possess one or more of these characters. No family of Salmoniformes has all of the primitive characters, but the families Salmonidae and Osmeridae have most of them.

Skeletal features

The primitive dentition pattern of the ancestral salmoniform would be with teeth on the premaxilla and maxilla (bones of the upper jaw) and on the dentary bone of the lower jaw, with the maxilla clearly dominant over the premaxilla in forming the gape of the upper jaw. Inside the mouth, on the upper surface, teeth would be on palatine and pterygoid bones on each side and on the median vomerine bone. On the lower surface of the mouth, teeth would cover the tongue and occur on a plate overlying the basibranchial bones (between the gill arches). Many separate lines of salmoniforms show evolutionary advancement for the loss of teeth and the dominance of the premaxilla over the maxilla, with loss of teeth on the maxilla.

The primitive structure of the pectoral girdle, associated with the ventral position of the pectoral fin, consists of an additional supporting bone—the mesocoracoid. The advanced condition, related to a more dorsally positioned pectoral fin, is the loss of the mesocoracoid.

The primitive salmoniform condition of the caudal skeleton has three separate vertebral centra (the centrum is the main body of the vertebra) and associated bony elements functioning in support of the bony plates (hypural plates), which form the base of the tail. Such a structure is a vestige of the upturned tail (heterocercal tail) characteristic of a more primitive stage of fish evolution. Other such vestiges found in some salmoniform fishes include abdominal pores (minute ducts from the body cavity to the exterior), remnants of a preteleostean type of intestine (spiral valve), and the absence of oviducts in females. Evolution in several salmoniform lines has reduced by fusion the three supporting caudal vertebrae to two or, more commonly, one. The primitive type of salmoniform swim bladder is connected to the esophagus by a duct. The absence of the duct or absence of the swim bladder is the advanced state. The primitive salmoniform had pyloric ceca on the intestine—a variable trait among living species. The light organs of some marine salmoniforms are an advanced character and are considered to be derived from mucous cells.

Annotated classification. The classification presented here is based on that of P.H. Greenwood *et al.*, with some modifications incorporated from more recent publications. These alterations consist of transferring the family Salangidae from the suborder Galaxioidei to the suborder Salmonoidei, placing the family Bathylaconidae in the suborder Alepocephaloidei (eliminating the suborder Bathylaconoidei), and the recognition of two additional families: Prototroctidae (in the suborder Galaxioidei) and Searsiidae (in the suborder Alepocephaloidei).

ORDER SALMONIFORMES

A diverse group of fishes with a mosaic of primitive characters. Typically fusiform or elongated predatory fishes. Adipose fin usually present; dorsal fin and pelvic fins typically placed midway along body; fin rays without true spines; pectoral fin generally in ventral position. Scales, if present, typically smooth (cycloid). Light organs present in several marine families. Caudal skeleton with 1 to 3 vertebral centra functioning in support of tail. Fossils from Cretaceous.

Suborder Salmonoidei

About 100 species; 10–150 cm (4 to 60 in.) long; freshwater, anadromous, or marine; Northern Hemisphere. Adipose present in all species; swim bladder with open duct; maxilla dominant over premaxilla in upper jaw; no light organs; intestine with pyloric ceca (except Salangidae); tail support on 3 distinct vertebral centra in Salmonidae, fused into single element in other families. Suborder includes the families Salmonidae (including Coregonidae and Thymallidae), salmons, trouts, chars; Osmeridae, smelts; Plecoglossidae, ayu; and Salangidae, icefishes.

Suborder Galaxioidei

About 50 species; 7.5–40 cm (3 to 15¾ in.) long; freshwater, anadromous, or catadromous; Southern Hemisphere. Adipose fin absent in Galaxiidae, present in other families; swim bladder with or without duct; relationship of maxilla and premaxilla variable among genera. Light organs absent. Pyloric ceca present or absent. Tail support on 1 or 2 vertebral centra; mesocoracoid bone of pectoral girdle absent; teeth present on mesopterygoid bone in roof of mouth. Suborder contains the families Galaxiidae, no group name; Retropinnidae, New Zealand smelts; Aplochitonidae, South American trouts; and Prototroctidae, New Zealand "grayling."

Suborder Esocoidei

Ten species; 5–150 cm (2 to 60 in.) long; freshwater; Northern Hemisphere. Adipose fin lacking; swim bladder with open duct; maxilla without teeth; pyloric ceca lacking; pectoral girdle without mesocoracoid bone; tail support on 3 separate vertebral centra; 2 sets of paired ethmoid bones on snout region of skull. Suborder includes the families Esocidae, pikes; and Umbridae (including Dalliidae), mudminnows.

Suborder Argentinoidei

About 50 species; 3–40 cm (about 1 to 15¾ in.) long; marine; worldwide. Adipose fin present on most species; swim bladder without duct or absent entirely; maxilla and premaxilla reduced, without teeth; light organs present in several species; tail support on 2 vertebral centra. Suborder includes the families Argentinidae (including Xenophthalmichthidae and Microstomatidae), argentines; Bathylagidae, deep-sea smelts; and Opisthoproctidae (including Dolichopterygidae, Macropinnidae, Winteridae), barreleyes.

Suborder Stomiatoidei

About 350 species; 2.5–45 cm (1 to 17¾ in.) long; marine; worldwide. Adipose fin present or absent, some species with both a dorsal and a ventral adipose fin; swim bladder without duct or absent entirely; maxilla the dominant bone of the upper jaw; some species with greatly enlarged, depressable teeth; anterior vertebrae sometimes unossified; light organs present in most families; members of some families with chin barbel, which may be a highly elaborate structure; tail support on single vertebral centrum. Suborder includes families Stomiatidae, scaly dragonfishes; Gonostomatidae, bristlemouths; Sternoptychidae, hatchetfishes; Astronesthidae, snaggletoothed fishes; Melanostomiatidae, scaleless dragonfishes; Chauliodontidae, viperfishes; and Idiacanthidae, black dragonfishes.

Suborder Alepocephaloidei

About 120 species; 3–700 cm (about 1 in. to about 23 ft); marine, deep-sea; worldwide. Adipose fin lacking; swim bladder lacking; teeth small; intestine with pyloric ceca. Light organs present in some species (on raised papillae). Tail supported by 3 vertebral centra. Suborder contains the families Alepocephalidae, smoothheads; Bathylaconidae, bony throats; Searsiidae, tubeshoulders; and Bathyprionidae.

Suborder Myctophoidei

About 470 species; 2.5–200 cm (1 in. to 6½ ft) long; marine; worldwide. Adipose fin usually present; swim bladder present in some species, if present, with duct. Premaxilla dominant over maxilla in upper jaw; no mesocoracoid bone in pectoral girdle. Light organs present in all species of family Myctophidae, but absent in species of most other families; tail support on single vertebral centrum. Suborder includes the following 15 families: Myctophidae, lantern fishes; Aulopodidae, thread-sail fishes; Synodontidae, lizard fishes; Harpadontidae, bombay duck; Chlorophthalmidae, green-eyes; Bathypteroidae, spider fishes; Ipnopidae, grid-eye fishes; Paralepididae, barracudinas; Omosudidae, hammerjaw; Alepisauridae, lancet fishes; Anotopteridae, javelin fish; Evermannellidae, sabre-toothed fishes; Scopelosauridae, paperbones; Neoscopelidae, blackchin; Scopelarchidae, pearleyes.

Alternate views on the nearest relatives of the salmoniforms

Critical appraisal. Previous schemes of fish classification have been based mainly on the work of the British ichthyologist C.T. Regan and the Soviet ichthyologist L.S. Berg. Both Regan and Berg grouped most of the generally primitive fishes with soft fin rays and smooth scales in an order with the herring family, Clupeidae. Regan called this order Isospondyli, and Berg used the name Clupeiformes. Such a classification considered Isospondyli or Clupeiformes as the most primitive of the teleostean fishes and as ancestral to all other advanced orders of Teleostei. The work of Greenwood and his colleagues clearly demonstrated that the classifications of Regan and Berg were without evolutionary reality, that the fishes classified as

Clupeiformes or Isospondyli, as formerly arranged, were not all derived from a common ancestor but consisted of several unrelated groups. The true herrings (family Clupeidae and their direct derivatives) possess some unique characters, such as the structures involved with the connection of the swim bladder to the inner ear, not found in any other teleostean fishes; the herrings thus are not very likely to have been the progenitors of all other modern teleosts. The order Salmoniformes was created to remove several diverse groups of dubious relationships from the order Clupeiformes; these groups are thus considered as the basal stocks in the evolutionary radiation of teleostean fishes. The order Iniomi of Regan (Scopeliformes of Berg) was placed as a suborder, Myctophoidei, in Salmoniformes. It should be emphasized, however, that this taxonomic revision has added little new knowledge concerning the relationships among the various suborders grouped in Salmoniformes. At present no coherent picture of evolutionary affinities among the suborders and with other orders has emerged. Undoubtedly the present interpretation of Salmoniformes will undergo major revisions in the future both in structure and in its implications regarding the evolutionary links leading to other teleostean orders. Publications by D.E. Rosen and by the British ichthyologist Colin Patterson consider new evidence and a more critical interpretation of previous data; they have separated the suborder Myctophoidei from the Salmoniformes into the order Myctophiformes and have suggested that the suborder Giganturoidei of the order Cetomimiformes should be placed in Salmoniformes. The myctophoid fishes are well separated from other salmoniforms, having undergone their own evolution at least since Cretaceous times (about 100,000,000 years ago)—fossil records of four families are known from Cretaceous deposits—and recognition of the order Myctophiformes seems justified.

Hopefully, new evidence will be forthcoming from future studies providing new insights into the evolutionary events that transpired from 50,000,000 to 100,000,000 years ago and resulted in the evolution of the various families and suborders of Salmoniformes. From such evidence, a better understanding of the ancient divergences leading to the bulk of the present teleostean fishes should follow. Ichthyologists may have exploited anatomical characters to the limit of potential information yield, but it is to be expected that new fossil finds of extinct, intermediate groups will yield valuable information.

New techniques for examining chromosomes and comparing their number, size, shape, and content and for comparing the structure of certain evolutionally stable protein molecules are promising approaches for the interpretation of evolution. (R.J.B.)

Characins, catfishes, minnows, carps, and allies (Ostariophysi)

The fishes of the superorder Ostariophysi include the majority of freshwater fishes throughout the world. Familiar representatives of this group are the minnows, suckers, characins, loaches, gymnotid "eels," and innumerable catfishes. The 31 recognized families of catfishes constitute the order Siluriformes, the remaining 26 families the order Cypriniformes. Humans consume huge quantities of these fishes for food and derive pleasure from the beauty of tropical aquarium fishes. A few harmful species can inflict painful injuries; some others serve as intermediate hosts for parasites of humans. Strange and fascinating behaviour is exhibited by many of these fishes—nest building, oral incubation, egg laying in mollusk shells, walking and flying, air breathing, production of sound and electricity, and communication by chemical secretions.

GENERAL FEATURES

Size range and diversity of structure. Most ostariophysians are small to moderate in size, from two to 30 centimetres (about one to 12 inches) long; others rank among the giants of the freshwater world. The elegant mahseer (Cyprinidae) of Asia grows to two metres ($6^1/_2$ feet) long and weighs 90 kilograms (200 pounds); the wels, a Eurasian catfish (Siluridae), attains a length of 4.5 metres (15 feet) and a weight of 300 kilograms (660 pounds). The extent of morphological diversity is at least as great as that in any other group of living vertebrates.

Ostariophysians abound in nearly all freshwater habitats, including subterranean caverns and those on all major landmasses and continental islands of the world except for Greenland and Antarctica. A few invade brackish waters, and two families consist largely of marine species. Approximately 6,000 species are recognized, about one-fourth of all known species of fish. Their undisputed success may be attributed at least in part to two remarkable features: a sense of hearing more acute than that in any other group of fish and a warning system by chemical communication unique among fishes.

Drawing by D.P. Janson

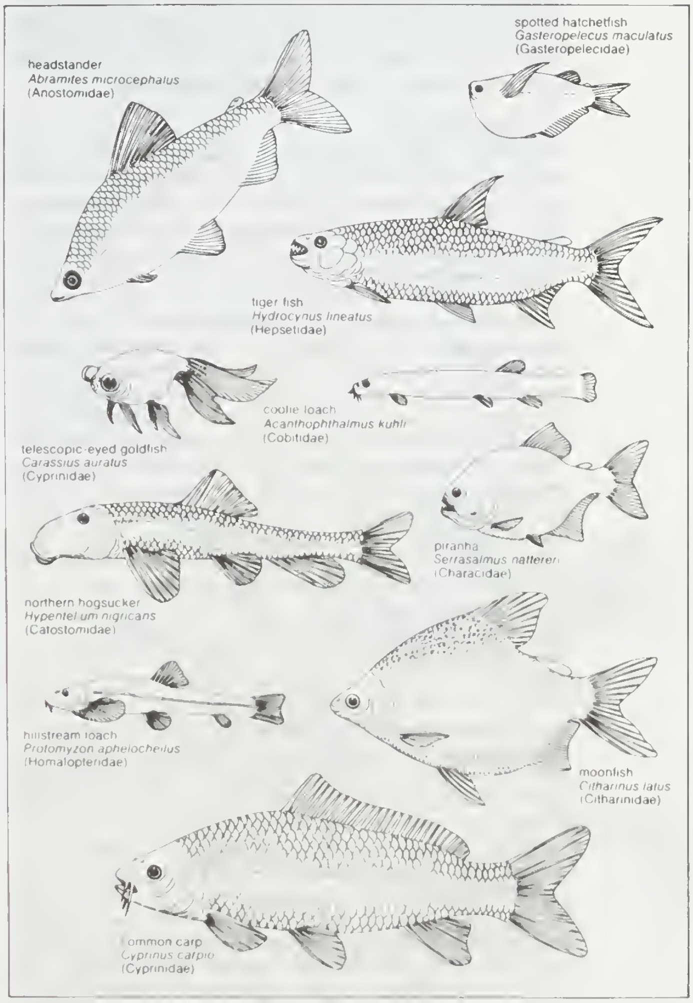

Figure 25: Body plans of representative ostariophysian fishes.

Importance. Many moderate to large ostariophysians are utilized for food, and commercial fisheries harvest huge quantities of marketable species. The common carp (*Cyprinus carpio*), originally from China, has been introduced nearly worldwide and is extensively cultured in the warmer regions. Other Chinese carp under cultivation include the grass carp (*Ctenopharyngodon*), silver carp (*Hypothalmichthys*), snail carp (*Mylopharyngodon*), and bighead carp (*Aristichthys*). Culture of the channel catfish (*Ictalurus punctatus*) is an important industry in the southern United States. Numerous ostariophysians provide sport fishermen with recreation and food; several rank among the world's prized game fish; *e.g.*, mahseers (several species of *Barbus*) of Asia and the dorado (*Salminus maxillosus*) of South America.

Among the most popular aquarium specimens are the characins, tetras, rasboras, danios, barbs, loaches, and innumerable catfishes. Adaptability of many ostariophysians to aquarium life has resulted in their widespread use as experimental animals in scientific research. Foremost among these are the goldfish (*Carassius auratus*) and the common carp.

In eastern Asia and parts of Europe,.humans frequently become infected with liver flukes acquired by eating raw or imperfectly cooked fish. The carps, especially *Ctenopharyngodon idellus,* are the second intermediate host of the Chinese liver fluke (*Clonorchis sinensis*). Many cyprinids serve as intermediate hosts for the cat liver fluke (*Opisthorchis felineus*). Domestic animals similarly become infected with flukes and tapeworms.

Some ostariophysians are pests or are potentially dangerous to man. The common carp is a nuisance in many localities in the United States. Introduced species such as the walking catfish (*Clarias batrachus*) pose a serious threat to the native fauna. In South America, on occasion, the piranha (*Serrasalmus*) voraciously attacks man and domestic animals, and the diminutive candiru (*Vandellia cirrhosa*) can penetrate the urogenital openings of human bathers and cause intense pain and hemorrhaging.

NATURAL HISTORY

Behaviour. *Reproductive cycle.* Like most fishes, ostariophysians are bisexual; eggs develop in the ovaries of the female and spermatozoa (milt) in the testes of the male. In temperate zones most species breed in the spring, when water temperatures are rising and day lengths (photoperiods) are increasing. In tropical regions many fishes spawn the year round. All ostariophysians lay eggs; none give birth to living young. Eggs are fertilized externally in the water in all species except a few auchenipterid catfishes and the South American characins of the subfamily Glandulocaudinae in which fertilization is internal. Development is direct; newly hatched individuals do not pass through morphological changes (metamorphosis) but instead are miniature replicas of their parents. The age at sexual maturity depends on the species and relative body size. Many small species reproduce when only a few months old and rarely live more than one to a few years. Large species attain sexual maturity when several years old, and, in captivity, the common carp has been known to live more than 50 years.

Breeding. Distinct pairing occurs in most ostariophysians, and courtship behaviour in characoids and cyprinoids often consists of elaborate displays by males in brilliant nuptial coloration. The eggs are heavier than water (demersal) and sink; most are sticky and adhere to the surface or to various objects. Characins and cyprinids generally deposit their eggs among aquatic plants, under stones and logs, or in shallow pits in gravel and sand. Among the many exceptions is the characin *Copeina arnoldi;* the female actually leaps out of the water to lay her eggs on the undersides of overhanging leaves (or, in captivity, of aquarium covers), to which she clings, joined by the male, during egg deposition. The parents then splash water on the eggs during development. The female bitterling (*Rhodeus sericeus*) deposits its eggs in the gill cavity of freshwater mussels by means of an elongated ovipositor, which she inserts into the mussel's incurrent siphon. Catfishes choose breeding sites in streams and ponds, generally in quiet water among plants or on mud, sand, gravel, or debris. The nest may be a simple circular depression (as in bullheads) or a tunnel-like affair in the bank (as in the channel catfish). Migrations comparable to those of salmon and eels are unknown among the ostariophysians, but the tendency to migrate occurs among suckers (Catostomidae), which swarm upstream into small tributaries and spawn over gravel or sand bottoms, and in other riverine species, as the mahseer (*Barbus tor*) and the African tiger fish (*Hydrocynus*).

Egg laying on leaves out of water

Parental care. Although many species exhibit no parental care, nest building and egg guarding are widespread among this group of fishes. Some cyprinids, such as the chubs (*Nocomis*), build massive pyramidal nests of stones; they desert the nests once spawning is completed. Other species of breeding minnows often swarm over these nests, and hybrids frequently are produced by the mixing of eggs and sperm from different species. The eggs of characids are commonly guarded by the male. Catfishes provide their eggs with considerable protection, either by guarding nests or by carrying the eggs with them. Oral incubation is practiced in sea catfishes (Ariidae); the male carries from 10 to 50 marble-sized eggs in the mouth cavity until hatching. The male continues to protect the hatchlings in his mouth even after the young have begun to feed independently. In certain species of banjo catfishes (Aspredinidae), the eggs are anchored to spongy tentacles on the underside of the female's abdomen. Some female callichthyid catfish carry eggs on the abdomen only for fertilization; others deposit their adhesive eggs in froth nests and guard them. The loricariid catfishes emply various methods; some lay adhesive eggs in cavities, others carry them under the lower lip, and a few deposit them on rocks, where they are cleaned, fanned, and guarded by the male.

Defense. Ostariophysians with bright colours and gaudy patterns are popular among tropical-fish fanciers; however, many other small species are somberly coloured, relying on this protective coloration for passive defense from enemies. Large carnivorous forms such as the African tiger fish and the South American piranhas have powerful jaws and strong teeth, extremely effective weapons for defense as well as for offense. Most catfishes and some Old World cyprinids possess spines (hardened fin rays) in the dorsal and pectoral fins. The spines alone afford a considerable degree of protection; in addition, venom glands develop at the base of the spines in some bullheads and madtoms of North America (Ictaluridae), labyrinthic catfishes (Clariidae), and sea catfishes (Ariidae and Plotosidae). Painful but rarely fatal injuries result when the skin of a victim is punctured and venom injected.

Protection by poisonous spines

Although a variety of freshwater fishes can generate an electrical charge, only two develop sufficient voltage to stun other animals, including man—the electric eel (*Electrophorus electricus*) and the electric catfish (*Malapterurus electricus*).

Ecology. *Habitat and distribution.* Ostariophysians are the dominant fishes in virtually all types of freshwater habitats throughout the tropical, temperate, and subarctic regions of the world. Only a few species of the families Cyprinidae and Aspredinidae are known to invade low-saline or brackish waters. The only truly marine members of this superorder are the sea catfishes (Ariidae and Plotosidae), which inhabit tropical coasts. Some plotosids, however, live in freshwater.

The upper regions of small mountain streams are characterized by steep gradients, waterfalls and rapids, and torrential currents. Here occurs a variety of ostariophysians (Homalopteridae, Sisoridae, Akysidae, Loricariidae, Astroblepidae), which exhibit fascinating structural adaptations, such as holdfast organs and specialized respiratory mechanisms. In river systems where the gradients are not steep, currents are slow and quiet pools alternate with riffles, large numbers of characins, cyprinids, and suckers and other types of catfish are conspicuous elements in the fauna. In the sluggish waters of large rivers live large species of suckers, cyprinids (*e.g.,* carp), and many catfishes generally characterized by environmental tolerances and nonrestrictive feeding habits. Ponds and lakes also support large populations of characids, cyprinids, catostomids, and siluroids that prefer and are adapted to standing-water habitats. Although a few are benthic (bottom-dwelling) forms, most of the characins and cyprinids tend to live and feed in the middle and upper layers of the water column. Suckers, loaches, and most catfishes are typically ethic animals and thus are highly adapted to such an existence. Catfishes are generally most active at night or under conditions of reduced light intensities.

Cave fishes

Among the most unusual habitats for fishes are those in subterranean waters, wells, and caves. A relatively large number of ostariophysians, belonging to unrelated families, present a striking example of convergent adaptation to life in more or less total darkness. The evolutionary trends have led to a reduction or loss of eyes, loss of pigment, and special development of certain sense organs, especially the lateral-line system, to compensate for the loss of sight. Ostariophysians adapted to such a mode of life include six genera of cyprinids in Africa, the Middle East, and Java; a characin (*Astyanax jordani*) from Mexico; ictalurids from the U.S. (*Trogloglanis* and *Satan*) and Mexico (*Prietella*);

six genera of pimelodids and trichomycterids from South America; and two genera of clariids from Africa.

Feeding habits. The remarkable diversity of feeding habits among ostariophysians is associated with a fantastic variety of adaptations in mouth shapes and tooth types (especially in the suborder Characoidei) probably unsurpassed by any other group. At one extreme are certain cyprinids (*e.g., Notropis atherinoides*) with highly developed gill rakers that strain phytoplankton (minute plants) from the water. Mountain-stream fishes (*e.g.,* Gyrinocheilidae, Homalopteridae, Loricariidae) possess suckerlike lips for scraping algae from the rocks; their teeth are minute or entirely lacking. Because they devour large quantities of plants, herbivores such as the Chinese grass carp are used experimentally to control vegetation in weed-choked waters. Omnivores are especially common among the characins and catfishes. Suckers, long-snouted knife fishes, many catfishes, and some minnows suck up mud and bottom debris, extract the nutriments, and eject the residue. Small carnivorous species consume insect larvae, small crustaceans, worms, mollusks, and other invertebrates. At the top of the food chain are the voracious predators, the most famous of which are the piranhas. Although modest in size, they have short, powerful jaws armed with razor-sharp teeth. These fearsome predators often occur in large schools and can quickly strip the flesh from their victims. Other fishes are their usual prey, but cattle and occasionally humans are also attacked. Probably the largest predatory ostariophysian is the tiger fish, which attains a weight exceeding 45 kilograms (approximately 100 pounds); its huge, sharp teeth and large, tunalike tail endow it with ferocity and speed. Parasitic habits are rarely found among bony fishes, but certain species of trichomycterid catfishes attach themselves to the gills of other fishes and feed on their hosts' blood.

Feeding habits of piranhas

FORM AND FUNCTION

Distinguishing characteristics. *Weberian apparatus and swim bladder.* The single character unique to the superorder Ostariophysi is the presence of the so-called Weberian apparatus, a complex connection between the inner ear and gas bladder (swim bladder). It is formed by the modification of the first four (or five) vertebrae immediately behind the skull, small portions of which have become separated and form a chain of four paired bones, or ossicles, named from front to back the claustrum, scaphium, intercalarium, and tripus. The first is in contact with a membranous window, or extension of the inner ear; the last touches the anterior wall of the swim bladder. The diverse modifications of the Weberian apparatus are diagnostic of orders and certain families; *e.g.,* the claustrum is absent in Gymnotidae. Although much remains to be learned about its functions, it is known to serve as a hearing organ. Changes in volume of the swim bladder due to sound waves in the water cause the ossicles to move and transmit pressure changes to the ear.

The gas bladder varies in shape and size but typically consists of two, sometimes three, chambers. In bottom-dwelling fishes, such as the Homalopteridae, Cobitidae, and many catfishes, the posterior chamber is greatly reduced and the anterior one often more or less surrounded by a bony capsule. In some catfishes (Sisoridae), only the anterior chamber remains, and it may be encapsulated with bone.

Body covering. The nature of the body covering is variable. Most cypriniforms possess cycloid scales (smooth, overlapping scales more or less circular in shape). Exceptions are found among the Ctenoluciidae, Distichodontidae, Citharinidae, and Ichthyboridae, which have ciliate, or ctenoid, scales (*i.e.,* posterior margins of scales with fine teeth). Most catfishes have lost the scaly covering and are naked, but several families possess bony plates forming an overlapping armour on the sides of the body (Doradidae, Callichthyidae, Loricariidae).

Bony armour

Fin spines and adipose fin. Ostariophysians possess segmented, branched, flexible, soft rays in the fins, unlike the stiff spines of perchlike fishes. In some species, however, soft-ray elements may fuse during development and give rise to a spinous ray (usually called a spine), commonly found in the dorsal and pectoral fins of most catfishes and in the dorsal and anal fins of some Old World cyprinids. The presence or absence of these spines is frequently diagnostic for genera and families.

An adipose fin consists of a small to elongated fleshy or fatty structure without fin-ray supports, located dorsally between the rayed dorsal fin and caudal (tail) fin. It is present in most ostariophysian fishes.

Barbels. Diverse morphological differences in the mouth region are related to the type of diet and to the modes of locating, capturing, and ingesting food. Barbels are short to filamentous, fleshy, fingerlike projections located at the corners of the mouth or on the snout and chin of many suctorial and bottom-feeding fishes (some minnows, loaches, and catfishes). Barbels are highly sensitive to touch, and they bear numerous taste buds. Taste and touch probably function together in the selection of food before ingestion.

Teeth. Teeth may be present along the jaws, in the roof of the mouth, on the tongue, or in the pharynx, or they may be entirely absent. In the minnows (Cyprinidae) and suckers (Catostomidae), the mouth is toothless, but an array of teeth is borne on a pair of branchial bones, the lower pharyngeals, located in the throat. In the minnows the pharyngeal teeth, arranged in one, two, or three rows, press or bite against a horny pad in the roof of the mouth. They have undergone specialization paralleling the diversity found in jaw teeth of other fishes. Vegetarians such as the carp have grinding, molar-like teeth; carnivores have pointed or hooked teeth. Suckers have numerous pharyngeal teeth aligned in a single row. Oral and pharyngeal teeth are of great value in classifying many families of ostariophysians.

Secondary sexual characteristics. With the onset of the breeding season, many secondary sexual characteristics

Drawing by D P Jenson

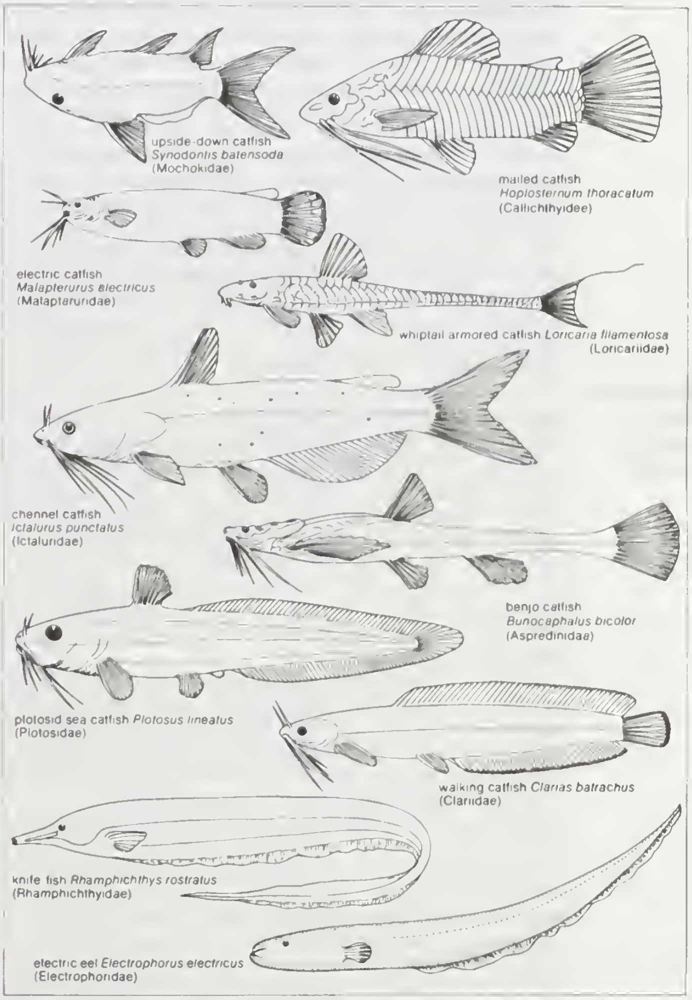

Figure 26: Body plans of representative ostariophysian fishes.

Sexual coloration

develop: size differences, nuptial coloration, enlarged and modified fins, breeding tubercles, and contact organs. These features are related chiefly to courtship and mating, but differences in size obviously play a role in guarding nests and care of the young; the sex that exercises parental care is usually the larger. Brilliant red, orange, yellow, green, and blue coloration may develop on various parts of the head, body, and fins, especially in the males. Some characids and cyprinids are among the most beautiful of all fishes. The male usually has larger and more brightly coloured fins than the female. In some characins, the median and pelvic fins of the males may possess small hooks or contact organs, which aid in maintaining contact with the female during spawning. In the six families of cyprinoids, breeding tubercles, or pearl organs (epidermal excrescences), develop on the head, body, and fins of males under the influence of sex hormones. The tubercles function in maintenance of body contact during spawning, in defense of nests and territories, and possibly in the stimulation of females during breeding.

Sexual differences among the siluroids are more marked in the highly specialized families. Pelvic fins of female ariid catfishes and, to a lesser extent, of ictalurid catfishes show specialized developments whose functions are not yet fully known. Some male loricariid catfishes develop elaborate dermal, branching growths and spines around the head; in others, the lower lip is enlarged to accommodate the transport of eggs.

Adaptations for locomotion. *Swimming.* The body of most ostariophysian fishes is more or less streamlined, taking the most efficient form for movement through water. In this highly diversified group, however, a large array of adaptations occurs. Lateral compression (flattened from side to side) is common, especially among characins and cyprinids that inhabit quiet, weedy lakes, ponds, and backwaters. Extreme examples are the flying hatchetfishes (Gasteropelecidae) and the knife fishes (Rhamphichthyidae and Apteronotidae). Depressed body form (flattened from top to bottom), especially in the head region, is widespread among fishes spending much time on or near the bottom or under rocks and similar objects (most catfishes) or among those inhabiting torrential mountain streams (Homalopteridae, some Loricariidae). An elongated, eellike form has evolved in certain loaches (Cobitidae) and electric eels (Electrophoridae), fishes that live on soft, muddy, and sandy bottoms or in rock crevices.

Departures from normal posture

The most common form of locomotion among ostariophysians is swimming by lateral undulations of the body, resulting from the contractions of muscles along the sides of the body and base of the tail. These undulating flexures culminate in a powerful back and forth sweeping of the caudal fin, which produces as much as 85 percent of the total thrust. Some fishes have departed from the normal horizontal swimming posture. The headstanders (Anostomidae) move with the head pointing downward at a slant; some of the pencil fishes (Hemiodontidae) assume a tail-standing position. Most bizarre of all are the upside-down catfishes (Mochokidae) of Africa, which can swim either in the normal position or inverted, with the belly uppermost. In *Synodontis batensoda,* the coloration of the belly is darker than the back, a reversal of the usual pigmentation pattern. Displacement of the gas bladder toward the underside is a further adaptation to this unusual swimming behaviour.

In fishes with specialized modifications of body form and habits, the fins are frequently modified and used for propulsion. The electric eels and knife fishes (Gymnotoidei) have lost the dorsal fin and, in some cases, the caudal fin. Slow forward and backward movements are made possible by undulations of an extremely long anal fin.

Associated with locomotion is the need for maintaining position in the water, particularly in the rapid torrents of mountain streams. A variety of modifications have evolved that function as holdfasts, anchoring the fish to rocks or similar objects. The hill-stream loaches (Homalopteridae) of southeastern Asia possess a large ventral suction disk formed by the expanded pectoral and pelvic fins. Some of the mountain-stream catfishes (Sisoridae) of Asia have an adhesive organ on the thorax (chest). Mountain-inhabiting catfishes of South America may use a suckerlike mouth (Loricariidae) or employ a combination of a disklike mouth and disklike paired fins (Astroblepidae) for adhesion to the surface.

Walking and flying. A few ostariophysians have the capability to emerge from their aquatic abode and move over land, climb walls, or even fly through the air. The walking catfish (*Clarias batrachus*), recently introduced into southern Florida, uses its pectoral-fin spines as anchors to prevent jackknifing as its body musculature produces snakelike movements and can progress remarkable distances over dry land. Using suction disks and fins, the mountain-stream catfishes (Sisoridae and Astroblepidae) can climb vertical rock walls above the water surface.

Flying by characins

The small hatchetfishes, or flying characins (Gasteropelecidae), of South America normally swim near the surface of the water but are capable of jumping clear and flying short distances. They vibrate enlarged pectoral fins rapidly back and forth by using highly specialized musculature on the shoulder girdle.

Air breathing. Although gills are typical respiratory structures in fishes, many freshwater species occupy habitats where the oxygen may be depleted occasionally or where droughts may force them to live out of water temporarily. These fishes have evolved a variety of airbreathing organs, most of which are outgrowths or pouches from the pharynx, branchial (gill) chamber, or digestive tube. Some catfishes (*Clarias* and *Heterobranchus*) of Asia and Africa have treelike respiratory structures extending above the gill chambers; others (*Heteropneustes*) have elongated, tubular, lunglike sacs extending backward as far as the tail. The electric eel is a mouth breather, gaseous exchange taking place through the wrinkled mucous membrane lining the mouth cavity. Some fishes actually swallow air into the lower part of the digestive tract, which then also serves as a respiratory structure. In the armoured catfishes (*Doras, Plecostomus, Callichthys*) of South America the thin-walled stomach serves this function. The loaches swallow air into a reservoir-like bulge from the intestine and void the remaining gases through the anus.

Communication and sensory perception. *Sound.* Sounds produced by ostariophysians are usually associated with the swim bladder. Minnows produce noises by expelling air through the pneumatic duct, which connects the gas bladder with the digestive tract, and the mouth; loaches do the same by expulsion through the anus. In several catfish families the expanded ends of a springlike mechanism (derived from modified portions of the fourth vertebra) are attached to the swim bladder. The contraction of muscles extending from the spring mechanism to the skull cause the springs and bladder wall to vibrate rapidly, producing a growling or humming noise. In other catfishes the rubbing or grating movements of the dorsal and pectoral spines produce sounds.

Hearing range

The sense of hearing in Ostariophysi is more highly developed than in any other fishes. The walls of the gas bladder are set in vibration by waves of underwater sound, and the Weberian ossicles then increase the amplitude of these vibrations, transmitting them to the internal ears. This combination is analogous to that of a hydrophone and endows these fishes with a remarkable sensitivity to sound. The normal frequency range detectable by ostariophysians is from 16 to 7,000 hertz (cycles per second); for some characins the maximum is 10,000 hertz. Among other functions, sound production and hearing in fishes may assist in bringing schooling fishes together; even more significant is the role of sound in reproduction. Experiments with North American cyprinids provide evidence that sounds are produced by both sexes and may serve for sexual recognition. A male is able to distinguish the calls of females of his own species from those of closely related species. Consequently, sounds may serve as isolating mechanisms in maintaining the genetic integrity of the species. For fishes living in muddy waters, sounds may be a vital communication link between individuals, especially in the breeding season. It is reasonable to suggest that the combination of sound production and acute hearing may have aided the ostariophysians in attaining their dominant role in freshwaters.

Production of electric currents

Electric organs. Members of the suborder Gymnotoidei and of the siluriform family Malapteruridae possess the unusual capacity to generate electricity. The best known and most powerful of this group is the electric eel (*Electrophorus electricus*). The electrical organs, three on each side of the body, are derived from modified muscle tissue. The force of the discharge has been measured at 350 to 650 volts and can produce a current strong enough to stun animals as large as a horse or man. The electric catfish (*Malapterurus electricus*) can deliver shocks up to 450 volts, but this power is apparently used only as a defensive measure. The electrical organ of this species, also derived from muscle tissue, consists of a specialized, gelatinous coat of tissue that sheathes most of the body just under the skin.

The gymnotid eels and knife fishes (*Gymnotus* and other genera) produce currents of low voltage only, emitting a continuous series of pulses (from 35 to 1,700 hertz), which create an electrical field around the fish. When this field is broken, either by a moving animal or by inanimate objects in the vicinity, the fish can locate the objects, which otherwise would be difficult to see at night or in muddy water. Experiments indicate that electrical cues may also facilitate social interactions. Perception of electrical stimuli occurs in specialized electrical receptors in the skin, and portions of the brain are enlarged to process electrosensory information.

Taste and smell. Catfishes and other fishes living in muddy waters have relatively poor vision but possess chemosensory acuity. Lips, barbels, and most of the body are covered with innumerable taste buds. Experiments have proved that taste plays a leading role in the location of food by these fishes.

Studies on the sense of smell have isolated odours emanating from mucus produced in the skin, from secretions of the gonads, and from other body parts. These odours, chemical signals called pheromones, provide a means of communication between individuals of the same or different species. Certain minnows (Cyprinidae) can discriminate between the odours of at least 15 species of fishes belonging to eight different families. The social behaviour of bullheads (*Ictalurus*) and other ostariophysians is related to a system of communications utilizing chemical signals. An individual not only recognizes individuals of other species but can identify and remember the identification of a particular individual of its own species after a time lapse of three weeks. Territorial and communal behaviour are evidently influenced by different pheromones.

Reactions to wounded companions

Alarm substances. In 1938 an Austrian biologist, Karl von Frisch, introduced an injured minnow (*Phoxinus*) into a school of the same species and observed that the school rapidly retreated and became very frightened. By experimentation he demonstrated that a chemical substance released from the lacerated skin produced a fright reaction when perceived through the nasal organs of other fishes. This "alarm substance," secreted by specialized cells in the epidermis, is released only when the skin is injured. Alarm substances are present in almost all species of ostariophysians tested (except for a few species of Characidae, Hemiodontidae, Chilodontidae, and Rhamphichthyidae) and are absent in all nonostariophysian fishes examined. Although the fright reaction appears to be important insurance for the individual against predation, the alarm substances are of greatest value among those species exhibiting social behaviour by warning other members of the school. It is possible that alarm substances and the fright reaction have contributed markedly to the biological success of the Ostariophysi.

CLASSIFICATION

Distinguishing taxonomic features. Many characteristics are useful in classifying this large, diverse superorder—the nature of the body covering; presence or absence of barbels, fin spines, and adipose fin; modifications of mouth and fins; types of teeth. Less obvious but especially significant are numerous skull features, specializations of the Weberian apparatus, configuration of the gas bladder, and fusions of vertebral elements.

Annotated classification. This classification, a recent revision by P.H. Greenwood (U.S.) and colleagues, raises to family rank many groups of fish often treated as subfamilies. The smallest families are grouped for brevity or are included under a closely related family.

SUPERORDER OSTARIOPHYSI

Gas bladder and internal ear connected by chain of ossicles (Weberian apparatus). All inhabit freshwater unless otherwise noted.

Order Cypriniformes

Body usually covered with cycloid scales; about 3,500 species.

Suborder Characoidei

Cretaceous (about 136,000,000 years ago to present). Mouth not protractile; jaws toothed. Characidae most generalized; other families have specialized skeletal structures, jaws, and teeth.

Family Characidae (characins). Fresh to brackish waters; Africa, South and Central America. Tremendous morphological and ecological diversity. Many brilliantly coloured. Variable food habits. Popular aquarium and food fishes. Size 2.5–150 centimeters (1–60 inches). Examples: tetras, piranhas.

Families Erythrinidae, Ctenoluciidae, and Cyndontidae. South America. Large mouths, canine teeth. Erythrinidae lacks adipose fin; Ctenoluciidae has ciliated scales; Cynodontidae, long anal fin. Carnivorous. Food fishes. Size to 120 cm (4 ft).

Family Hepsetidae. Africa. Pikelike; large canine teeth. Carnivorous. Food fishes. Size to 100 cm (40 in.), 55 kilograms (120 pounds).

Family Lebiasinidae. South and Central America. Lateral line and adipose fin usually absent. Small to moderate-sized predators.

Family Gasteropelecidae (hatchetfishes). South and Central America. Deep, strongly compressed body; pectoral fins with well-developed musculature. Capable of true flight. Insectivorous. Aquarium fishes. Size to 10 cm (4 in.).

Family Anostomidae (headstanders). South America. Elongated snout; small mouth with folded or fleshy lips or sucking disk. Head-standing habits. Herbivorous. Aquarium and food fishes. Size to 40 cm (16 in.). The South American families Prochilodontidae (predorsal spine, rough scales), Curimatidae (toothless jaws), and Chilodontidae (specialized pharyngeal teeth) are similar to the Anostomidae.

Family Hemiodontidae (pencil fishes). South and Central America. Lower jaw toothless. Tail-standing posture. Herbivorous. Aquarium fishes. Size to 20 cm (8 in.). Family Parodontidae is similar.

Family Citharinidae (moonfishes). Africa. Deep-bodied, scales often denticulate (toothed), small mouth and teeth. Herbivorous. Aquarium and food fishes. Size to 90 cm (3 ft). The African families Distichodontidae (upper jaw not or scarcely movable) and Ichthyboridae (slender body, upper jaw freely movable, carnivorous) are similar but have ctenoid (ciliate) scales.

Suborder Gymnotoidei

No fossil record. Body elongated; anal fin very long; electric organs present.

Families Gymnotidae (gymnotid eels), *Apteronotidae, and Rhamphichthyidae* (knife fishes). South and Central America. Body greatly compressed, scaled Weak electrical powers. Rhamphichthyidae with elephant-like snout; herbivorous. Other families carnivorous. Size to 90 cm (3 ft).

Family Electrophoridae (electric eels). South America. Body eellike, scaleless. Powerful electric organs. Size to 275 cm (about 9 ft), weight to 22 kg (48 lb).

Suborder Cyprinoidei

Paleocene to present. Mouth toothless, protractile. Adipose fin rarely present.

Family Cyprinidae (minnows and carps). Most in fresh but some in brackish water; Asia, Europe, Africa, North America. Pharyngeal teeth in 1 to 3 rows. Some with 1 or 2 pairs of small barbels. Food habits variable. Food fishes of sport and commercial value; aquarium fishes. Size 2.5–250 cm (1 in. to more than 8 ft). Examples: minnows, carp, goldfish, barb, bitterling.

Family Catostomidae (suckers). North America, Asia. Protractile, sucking mouth on underside of head. Detritus feeders. Food fishes. Size to 90 cm (36 in.).

Families Gyrinocheilidae (algae eaters), *Psilorhynchidae, and Homalopteridae* (hill-stream loaches). Mountain streams, Asia. Adaptations to fast currents include fleshy, suctorial mouth and inhalant–exhalant gill openings (Gyrinocheilidae); ventral sucking disk formed by paired fins (Homalopteridae). Algae feeders. Size to 10 cm (4 in.).

Family Cobitidae (loaches). Asia, Europe, Africa. Wormlike;

scales minute or absent; barbels 3–6 pairs. Intestine sometimes modified for aerial respiration. Mostly carnivorous. Aquarium fishes. Size to 30 cm (12 in.).

Order Siluriformes (catfishes)

Paleocene to present. Body naked or covered with bony plates; adipose fin usually present; pectoral and dorsal fins often with spines. Mostly omnivorous. About 2,500 species.

Family Diplomystidae. South America. One pair of barbels; primitive Weberian apparatus. Size to 24 cm (9½ in.).

Family Ictaluridae (North American freshwater catfishes). Few enter brackish water. North America; widely introduced. Barbels 4 pairs; some with venom glands. Valuable food fishes (sport and commercial). Size to 170 cm (67 in.), 50 kg (110 lb). Examples: bullhead, channel catfish.

Family Bagridae. Found in Asia and Africa. Similar to Ictaluridae but with elongated adipose fin. Food, aquarium fishes. Size to 90 cm.

Family Siluridae. Asia, Europe, Africa. Body compressed; adipose fin lacking, anal fin very long; short dorsal fin (often lacking) without spine. Food; aquarium fishes. Size to 400 cm (13 ft), 300 kg (660 lb). Examples: wels, glass catfish.

Family Schilbeidae. Asia and Africa. Similar to Siluridae, but with adipose fin usually present and spine in dorsal fin. Food fishes. Size to 230 cm (91 in.), 110 kg (240 lb).

Families Amblycipitidae and Akysidae. Asia. Similar to Bagridae but with reduced gas bladder. Akysids inhabit mountain streams, have tuberculated skin. Small size.

Family Amphiliidae. Africa. Similar to Bagridae, but paired fins expanding horizontally for adhesion in fast currents. Size to 21 cm (8½ in.).

Family Sisoridae (mountain-stream catfishes). Asia. Ventral surface flat; thorax with longitudinal plates or adhesive organ. Size to 30 cm (12 in.).

Family Clariidae (labyrinthic catfishes). Asia, Africa; widely introduced elsewhere. Long dorsal and anal fins without spines; adipose fin usually lacking. Treelike air-breathing organ. Food fishes. Size to 130 cm (51 in.). Example: walking catfish. The similar family Heteropneustidae has long, hollow air sacs.

Families Cranoglanididae, Pangasiidae, Chacidae, and Olyridae. Small Asian families, each containing 1 to several species.

Family Malapteruridae (electric catfishes). Africa. Rayed dorsal fin lacking; spines lacking. Electric organs. Food fishes. Size to 120 cm (47 in.), 23 kg (50 lb).

Family Mochokidae (upside-down catfishes). Africa. Bony shield on head and nape. Some swim upside down. Food fishes. Size to 60 cm (24 in.).

Families Ariidae and Plotosidae (sea catfishes). Marine, a few entering freshwater. Tropical coasts; Plotosidae restricted to Indo-Pacific. Nasal barbels lacking; oral incubation of eggs (Ariidae). Adipose fin lacking; long anal and caudal fins confluent (Plotosidae). Food fishes. Size to 115 cm (45 in.).

Family Doradidae (thorny catfishes). South America. Overlapping plates cover sides of body. Intestinal modifications for aerial respiration. Aquarium fishes. Generally small, to 100 cm (40 in.). The related family, Auchenipteridae, has naked flanks and apparent internal fertilization.

Family Aspredinidae (banjo catfishes). A few enter brackish waters and salt waters. South America. Adipose lacking; broad, flat head; large tubercles on naked body. Aquarium fishes. Size to 30 cm (12 in.).

Family Pimelodidae. South and Central America. Similar to Bagridae but lack nasal barbels. Food, aquarium fishes. Size to 130 cm (51 in.), 65 kg (145 lb). Families Ageneiosidae (maxillary barbels only), Hypophthalmidae (1 species, toothless), and Helogeneidae (1 species, no dorsal spine) are South American families similar to the Pimelodidae.

Family Trichomycteridae (parasitic catfishes). South America. Operculum (gill cover) usually with spines. Many parasitic. Size to 10 cm (4 in.). Example: candiru. The similar family Cetopsidae lacks opercular spines.

Families Callichthyidae (mailed catfishes), *Loricariidae* (armoured catfishes), *and Astroblepidae.* South and Central America. Two longitudinal series of overlapping bony plates in Callichthyidae. Three or 4 rows of bony scutes in Loricariidae. Skin naked in Astroblepidae. Sucking mouth (Loricariidae), or mouth and fins modified for adhesion to rocks in mountain streams (Astroblepidae). All herbivores, closely related. Aquarium fishes. Size to 75 cm (30 in.).

Critical appraisal. Ostariophysians are relatively primitive bony fishes, singularly distinct from all other fishes except the Gonorynchiformes. Their specialized Weberian apparatus precludes their having given rise to any higher groups. Differences among various classifications of the superorder are not as great as they appear; the same or similar subgroups are widely recognized, but they may be assigned to different levels in the taxonomic hierarchy. L.S. Berg placed all ostariophysians in one order (Cypriniformes) with two divisions (Cyprini and Siluri). The many families of characins listed by Greenwood are recognized as subfamilies under the single family Characidae by many authorities. Present consensus favours the characoids as the most primitive suborder, an ancestral stock giving rise to cyprinoids in southeastern Asia and to gymnotoids in South America.

The siluriform fishes are more highly specialized than the cypriniforms, and the diplomystids undoubtedly are the most primitive of the catfishes. There is little agreement on the relationships of the other families, but recent research on the caudal skeleton indicates that the Ictaluridae, Bagridae, and Schilbeidae (among others) tend to retain primitive characteristics. Advanced features indicate a relationship between the Clariidae and Heteropneustidae; the Doradidae and Auchenipteridae; the Loricariidae, Astroblepidae, and Callichthyidae; and the Plotosidae and Chacidae. Extensive studies of morphological and other genetic characters of both cypriniform and siluriform fishes are needed before a satisfactory classification and phylogeny can be achieved. (R.W.Y.)

Toadfishes, trout-perches, codfishes, and allies (Paracanthopterygii)

The fishes that constitute the superorder Paracanthopterygii are a predatory, primarily marine group that forms one of about six major branches of the Teleostei, or bony fishes, the dominant modern aquatic vertebrates. Approximately 1,160 living species of paracanthopterygian fishes have been described; they range in length from just a few centimetres to roughly two metres (more than six feet).

In general body form there is considerable diversity, but ichthyologists have classed the Paracanthopterygii as a discrete group, largely on the basis of a distinctive musculature of the jaws, the structure of the caudal (*i.e.,* at the tail end) vertebrae, and the placement of the pelvic fins (they are usually in the midbody region or even farther toward the head).

The Paracanthopterygii comprises six orders: Batrachoidiformes, or toadfishes, about 45 species; Gadiformes, or codfishes, about 800 species; Gobiesociformes, or clingfishes, about 100 species; Lophiiformes, or anglerfishes, about 210 species; Percopsiformes, or trout-perches, about eight species; and Polymixiiformes, or beardfishes, three species. Most of the orders are primarily marine, with worldwide distribution; the percopsiforms, however, occur only in fresh waters of North America. Batrachoidiforms and gobiesociforms occur mainly in tropical and temperate shallow water along continental coasts and to a limited extent in fresh water. Gadiforms are represented by both shallow-water and deep-sea types. The most widely known gadiforms are the commercially important species and the only economically important paracanthopterygians: the true cods (*Gadus*), hakes (*Merluccius, Urophycis*), haddocks (*Melanogrammus*), pollocks (*Pollachius*), and whitings (*Merlangius*). All are abundant in waters of the continental shelf of the North Atlantic, where they have been commercially fished for centuries from both Europe and North America. Lophiiforms live in shallow waters of tropical reefs as well as in the ocean depths. Polymixiiforms occur at moderate depths in most warm seas, generally near continents.

Size range

The largest of the Paracanthopterygii are the codfishes, which grow to about two metres in length and attain weights that may exceed 90 kilograms (about 200 pounds). Certain goosefishes (Lophiiformes) reach a length of about two metres and a body weight of 35 kilograms (about 75 pounds); other lophiiforms are as small as 2½ centimetres (about one inch) long. Batrachoidiforms grow to about 30 centimetres (one foot) in length, gobiesociforms to about eight centimetres (three inches). The largest percopsiforms are about 15 centimetres (six inches) long. Polymixiiforms reach no more than 30 centimetres in length.

NATURAL HISTORY

Life cycle and reproduction. Eggs of the oyster toadfish (*Opsanus tau*) of the western Atlantic—one of the most carefully studied batrachiforms—are laid in dark recesses of all sorts, including sunken tin cans and shoes. The male guards the eggs and young for about three weeks, after which the young fishes begin life on their own. The fish gets its name from the fact that some have been found living in living oysters. Luminous organs known as photophores, numbering several hundred and set in long horizontal rows, are believed to be sexual attractants in the midshipman (*Porichthys*)—so named because the organs resemble rows of bright buttons on a naval uniform. The northern midshipman (*P. notatus*), a common species on the eastern Pacific coast, spawns in shallow water, attaching its eggs to a rocky surface. The male guards the eggs. Like other batrachoidiforms, the midshipman lives and grows on the ocean bottom.

Parasitic habit of pearlfish

Most species of codfishes (which comprise some 70 species of Gadiformes) migrate over long distances. They gather in late winter and early spring to spawn, each species going to a particular area. The periodic movements are closely related to seasonal variations in water temperature. Fecundity of some codfish species is prodigious. The European ling (*Molva molva*) may deposit as many as 60,000,000 eggs each season. The eggs and larvae of most species are found in the plankton (*i.e.*, the aquatic organisms, collectively, suspended in the sea). Weeks or months elapse before the eggs hatch. Young codfishes are commonly found in very shallow water, but they move into deeper water as they become older. The eggs of grenadiers (family Macrouridae), a bottom-feeding group of cods, are believed to be laid near the bottom; the buoyant eggs rise part way to the surface. The larvae are known mainly from below 100 fathoms (about 180 metres, or 600 feet); older larvae occur at greater depths. In the Mediterranean pearlfish (*Carapus acus*), a member of another codlike group (family Carapidae), clumps of eggs, released by the female in late summer, appear at the surface and hatch into a specialized larva, the vexillifer, which lives amid the plankton. After attaining a length of about seven to eight centimetres (about three inches), it transforms to another larval stage, the tenuis, descends to the bottom, and becomes a parasite in a sea cucumber (*Holothuria tubulosa* or *Stichopus regalis*). The tenuis, apparently dependent upon its host for survival, undergoes a further transformation to the juvenile stage; in the process, its length decreases from 20 to 10 centimetres (eight to four inches). The Mediterranean pearlfish is believed to pass most of its life in the host. Very little is known of the general biology of reproductive habits of the brotulas and cusk eels (family Ophidiidae), also of the cod group. They are both oviparous (egg-laying) and viviparous (live-bearing). The males of some viviparous species produce spermatophores (sperm cases). The European eelpout (*Zoarces viviparus*) of the cod family Zoarcidae bears living young about five centimetres in length and numbering as many as 400. Fertilization is internal, and embryonic development occurs in the ovary of the female. Other eelpouts are believed to be live-bearing, but the ocean pout (*Macrozoarces americanus*) of the western Atlantic lays eggs that are guarded by one or both parents.

Drawing by J. Helmer based on (cave fish) N.B. Marshall, *The Life of Fishes* (1965), Weidenfeld and Nicolson Co. Ltd., London, (all but *Polymixia*) David Starr Jordan, *A Guide to the Study of Fishes*, Holt, Rinehart & Winston, Inc.

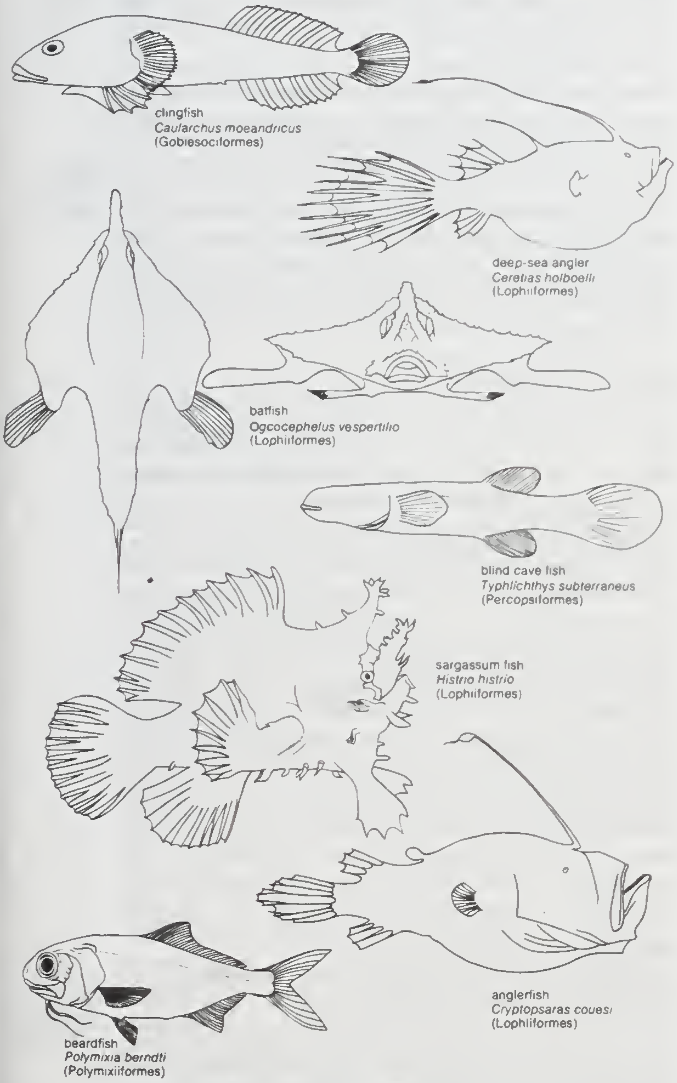

Figure 27: Body plans of representative members of the orders Gobiesociformes, Lophiiformes, Percopsiformes, and Polymixiiformes.

Parasitism of male anglerfish

The lophiiforms are primarily bottom fishes as adults, but many produce floating rafts of eggs. The eggs of the deep-sea anglerfishes (suborder Ceratioidei) are unknown; but it is believed that they float to the surface; the larvae occur in surface waters, gradually descending to deeper waters as they grow older. The females of the deep-sea anglers are from three to 13 times as large as the males. Females have an illicium, or "fishing pole," which is a modified spine of the dorsal, or back, fin that has moved forward onto the top of the head. At the tip of the illicium is a fleshy enlargement, the esca, used to lure prey within range of capture. (The illicium and esca are generally present also in male anglerfish other than in the Ceratioidei.) Commonly the esca is luminous; the female also has other light-producing organs. In 1922 a specimen of the anglerfish *Ceratias holboelli* was discovered; small specimens attached to its abdomen were thought to be its young. A few years later similar finds led to the discovery that the smaller fish were really mature males living parasitically on the female. Further investigation showed that the males, soon after their transformation from the larval state, bite onto an older, larger female, after which the female and male tissues unite; the separate circulatory systems join; and the male becomes a permanent appendage of the female.

Little is known of the reproductive habits of the gobiesociforms, percopsiforms, or polymixiiforms. Gobiesociforms are known to lay eggs in shallow water, attaching them to rocks or plants; and percopsiforms are known to spawn in the spring of the year in shallow water.

Ecology and behaviour. All batrachoidiforms are bottom dwellers. True toadfishes (Batrachoidinae, about 25 species) occur in shallow or moderate depths along continental coasts; some ascend rivers. The oyster toadfish lives under rocks or amid debris, awaiting prey of almost any type, which is taken with a sudden snap. Venomous toadfishes (Thalassophryninae, about nine species) are restricted to the coasts and rivers of Central and South America. Because of their sluggish habits, these fishes are sometimes stepped on by man and can inflict painful wounds. Midshipmen (Porichthyinae, about 12 species), which are restricted to tropical and temperate coasts of

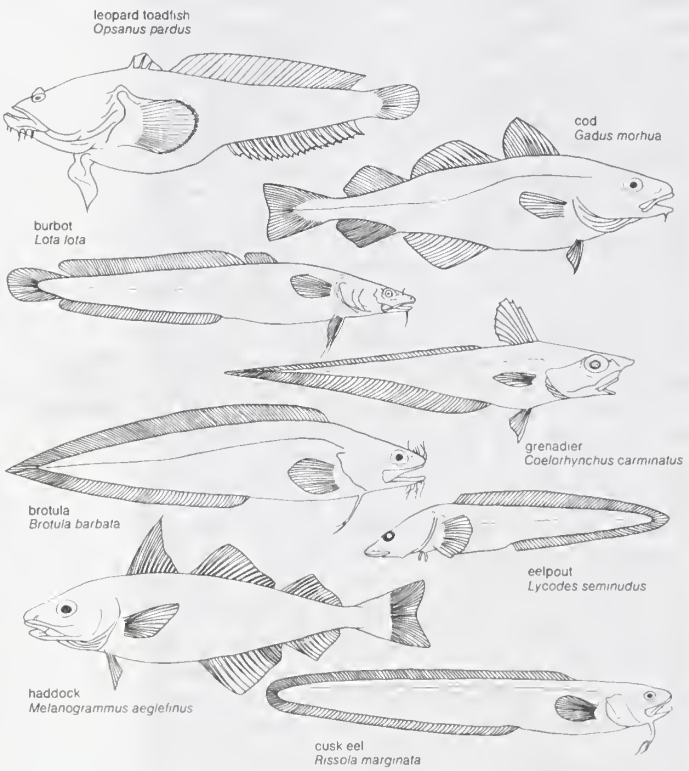

Figure 28: Body plans of representative members of the orders Batrachoidiformes (toadfish) and Gadiformes.

Drawing by J. Helmer from David Starr Jordan, *A Guide to the Study of Fishes*, Holt Rinehart & Winston, Inc

the Americas, are unusual in being shallow-water fishes with photophores, a feature generally found in deepwater forms. Most midshipmen occur in depths of less than 50 fathoms (one fathom = six feet), and all are found in water shallower than 200 fathoms.

Gadiform fishes of the family Gadidae (about 70 species) are all marine species, except for the burbot (*Lota lota*); some, however, ascend rivers with the tides. Bottom dwellers, they occur on the continental shelves from shallow water to about 200 fathoms and, although distributed throughout the oceans, are most numerous in the eastern North Atlantic. Deep-sea cods (Moridae, about 70 species) are cold-water bottom fishes, living at greater depths along the continental slopes. Grenadiers (Macrouridae, about 300 species), typically bottom fishes, live along the continental slopes at depths of 100 to 1,000 fathoms. Few species are cosmopolitan in distribution, but the group as a whole is widely distributed in tropical and temperate latitudes. A few species of gadiforms (Muraenolepididae, four species) are confined to Antarctic seas, and, like the cods, they are bottom fishes, living at moderate depths. The pearlfishes (Carapidae, about 27 species) are marine, mainly tropical, shallow-water, eellike fishes adapted to living inside the body of various invertebrates. They have been collected from a variety of hosts, including tunicates, oysters, and sea cucumbers. Brotulas and cusk eels (Ophidiidae, about 250 species) are mainly bottom dwellers. Some are shallow-water species with nocturnal habits, but the group as a whole is the dominant teleostean family at depths greater than 2,000 fathoms. Some have been taken at depths of about 4,000 fathoms, the greatest depth at which any form of fish life is known. Eelpouts (Zoarcidae, about 80 species) are bottom fishes, commonly occurring from shallow water to depths of 1,000 fathoms. Species are most abundant in the higher latitudes of both hemispheres, especially in the north. Eelpouts are common in shallow water of Arctic and Antarctic seas.

Eelpouts

Gobiesociforms (about 100 species) are mostly marine fishes, typically inhabiting the intertidal zone. Some species (*Diademichthys*) hide among the spines of sea urchins. In tropical America, four species (*Gobiesox*) are known from swift-flowing freshwater streams.

Of the lophiiforms, the ceratioids, or deep-sea anglerfishes, are the only abyssal (deep-sea) forms. They occur primarily at depths of 1,000 to 3,000 fathoms. Unlike other lophiiforms, they are midwater fishes, are uniformly black, and have no pelvic fins. They are apparently feeble swimmers, depending primarily on their light organs to attract prey. Some (*Melanocetus, Linophryne*) are known to swallow fishes several times their own length, accommodating them in a highly distensible stomach. Crustaceans and other invertebrates are also eaten. Many lophiiforms—so-called·frogfishes (Antennariidae, about 60 species)—are shallow-water forms, commonly inhabiting coral reefs. Frogfishes typically have highly varied colour patterns, and some species are able to change colours. In habit they are sedentary but can use their fins to walk on the bottom and to climb over obstacles. The tropical sargassum fish (*Histrio histrio*), so called because it lives amid floating brown algae of the genus *Sargassum*, clings to the branches of algae with prehensile (*i.e.*, adapted for seizing, or wrapping around) pectoral fins as it searches for prey, which is sucked into the mouth by the powerful jaws and expandable cheeks.

The lophiiform group known as goosefishes (Lophiidae, about 12 species) seldom occur in shallow water, preferring instead the moderate depths (10 to 500 fathoms) along the continental slopes of tropical and temperate region. The batfishes (Ogcocephalidae, about 60 species), are mainly deepwater lophiiforms, but some (*Ogcocephalus, Halieutichthys*) are regularly found in water only a few feet deep. Like frogfishes, they walk on the bottom, using their pectoral fins. Batfishes are awkward swimmers and, when disturbed, tend to bury themselves in the bottom rather than swim away.

Percopsiforms (about eight species) live under conditions of dim light. Cave fishes, with eyes reduced to nonfunctional rudiments, have elaborate systems of sense organs in the skin of the head, body, and tail; they live in total darkness. Because of the secretive habits of percopsiforms, little is known about species other than the trout-perch (*Percopsis omiscomaycus*), which is widely distributed in central North America and is abundant in some of the Great Lakes, where it occurs in clear water to a depth of about 35 fathoms. Polymixiiforms, numbering only three marine species, are generally found at depths of 150 to 350 fathoms.

Fishes without eyes

FORM AND FUNCTION

Batrachoidiforms generally have two dorsal fins; a small anterior fin, usually with two spines; and a long posterior fin. In venomous species, the hollow fin spines form an efficient apparatus for the injection of venom. A similar spine is found on each cheek (operculum).

Among the gadiforms, the dorsal and anal fins of some deep-sea cods are distinctively arranged as three dorsals and two anals. This arrangement also occurs in some codfishes (Gadidae). The macrourids are characterized by a long, tapering tail. A tubular light organ containing luminescent bacteria is sometimes present along the ventral midline of both sexes. All but a few species of macrourids have a well-developed swim bladder; in the males of some species and in some codfishes, the swim bladder is equipped with drumming muscles, indicating that sound can be produced. In the bregmacerotids and muraenolepidids there are two dorsal fins, with the anterior fin represented by a single ray. Brotulas may have the pelvic fins either present or absent, but cusk eels have them anterior in position, under the lower jaw. They are kept in continuous probing motion, as the fish swims just off the bottom, and aid in detecting food. Zoarcids (eelpouts) are elongated, eel-like fishes. Their pelvic fins are either rudimentary or entirely absent.

Gobiesociforms, with a depressed head, wide mouth, and tapering body, resemble toadfishes, but they are distinctive in having a prominent sucking disk on the ventral surface. The paired pelvic fins, thoracic in position, form part of the disk, various fleshy pads and folds forming the remainder. The disk allows clingfishes to hold fast to rocky bottoms amid the often turbulent wave action of their shallow-water environment.

Suction disk for attachment to bottom

Some lophiiforms are unique among teleostean fishes in having only two gills. The ogcocephalids are somewhat flattened anglers, in this respect resembling lophiids rather than the ballon-like antennariids; they are distinctive in having the illicium, when not in use, concealed in a tube (illicial cavity) between the eyes and over the mouth. Like most anglerfishes they lack typical scales but are distinctively equipped with bony tubercles (projections) and spines imbedded in the skin.

The polymixiiforms are singular in having a pair of fleshy barbels, or "whiskers," under the jaw. Each barbel is supported by three small bones.

EVOLUTION AND PALEONTOLOGY

Fossil batrachoidiforms include only material from lower Pliocene marine deposits (about 5,000,000–7,000,000 years old) of North Africa. These fossils are similar to a living species, *Batrachoides didactylus.*

Fossil gadiforms are relatively numerous and are known primarily from Tertiary marine deposits (about 2,500,000–65,000,000 years old) of the Northern Hemisphere. A Paleocene fossil (54,000,000–65,000,000 years old) has been identified as a codlike fish; some Eocene fossils (38,000,000–54,000,000 years old) have been identified for the families Bregmacerotidae and Gadidae; and Oligocene–Miocene fossils (7,000,000–38,000,000 years old) for the families Bregmacerotidae, Gadidae, Macrouridae, and Ophidiidae. In addition, many fossil ear stones (otoliths) and scales, beginning with specimens from the Cretaceous (65,000,000–136,000,000 years ago), are similar to the Gadiformes. Fossil gobiesociforms are unknown. Fossil lophiiforms include two species from Eocene marine deposits of Europe and one species from Pliocene marine deposits of North Africa; one Eocene species has been identified as a goosefish (Lophiidae), the other as a frogfish (Antennariidae).

Fossil percopsiforms include three genera from Tertiary freshwater deposits of North America and one (*Sphenocephalus*) from Cretaceous marine deposits of Europe. Of the North American genera, two (*Amphiplaga, Erismatopterus* from the middle Eocene) have been identified as trout-perches (Percopsidae), and one (*Tricophanes,* Oligocene–Miocene) as a pirate perch (Aphredoderidae). The relationships of *Sphenocephalus* are obscure. Fossil polymixiiforms include a diversified group of about six genera known primarily from Cretaceous marine deposits of Europe and the Middle East; a few others are known from the Tertiary.

CLASSIFICATION

Annotated classification.

SUPERORDER PARACANTHOPTERYGII

Most with a distinctive type of jaw musculature (involving levator maxillae superioris muscle and associated structures); pelvic fins usually placed anteriorly, thoracic (midbody) or even further forward; primarily marine; worldwide distribution; about 1,600 living species.

Order Polymixiiformes (beardfishes)

Middle Cretaceous to Recent. Barbels supported by rays; spines on the dorsal and anal fins; pelvic fins subthoracic. Deepwater marine fishes; three species. Adult length about 30 cm (12 in.).

Order Percopsiformes (trout-perches, pirate perches, and cave fishes)

Eocene to Recent. Mouth gape and buccal dentition reduced; median fin spines reduced or lost; head with spine ornamentation. About 8 living species, all freshwater; North America; length 8–15 cm (3 to 6 in.).

Order Gadiformes (cods, cusk eels, pearlfishes, eelpouts, and grenadiers)

Paleocene to Recent. Early gadiforms were similar in structure to early percopsiforms, but almost all remained marine and subsequently specialized into a variety of environments. Reduced caudal skeleton; elongate body; altered head and jaw structure. Very reduced fin spines; marine, worldwide. About 800 species. Length 7 to about 200 cm (2¾ in. to 6½ ft).

Order Batrachoidiformes (toadfishes)

Miocene to Recent. Bottom fishes with short, small, spinous dorsal fins; long soft-rayed dorsal fins; flat heads; about 45 species; marine, occasionally freshwater, shore fishes of tropics. Length to about 30 cm (12 in.).

Order Lophiiformes (goosefishes, anglerfishes, frogfishes, and batfishes)

Eocene to Recent. Spinous dorsal fin modified as a movable lure. Some deep-sea forms with light organs and males parasitic on females. Marine, widespread; in shallow-water and deep-sea habitats. About 210 species. Length to about 200 cm (6½ ft).

Order Gobiesociformes (clingfishes)

Recent; flattened, depressed fishes with a ventral sucker formed of the pelvic fins and surrounding tissue; no spiny dorsal fin; about 100 species; marine and occasionally freshwater in tropics and along many temperate seacoasts.

Critical appraisal. The interrelationships of the groups listed here as paracanthopterygians are not yet well established, and the classification given here is provisional. There is considerable agreement that trout-perches (Percopsiformes) and cods (suborder Gadoidei) are closely related, and this agreement may be considered the basis of the group Paracanthopterygii. What other fishes should be included in the Paracanthopterygii is a question receiving continued study. Some ichthyologists have held that clingfishes (Gobiesociformes) are related to dragonets (Callionymidae); that eelpouts (Zoarcidae) are related to blennies (Bathymasteridae, Blenniidae, etc.); that brotulas, cusk eels, and pearlfishes (suborder Ophidioidei) are related to the river blackfish of Australia (the perchlike *Gadopsis*); that beardfishes (Polymixiiformes) are related to squirrelfishes and their relatives (Beryciformes); and that toadfishes (Batrachoidiformes) and anglers (Lophiiformes) also have their relationships within the great mass of perchlike fishes (Acanthopterygii). In addition, killifishes (Cyprinodontidae) and related live-bearers (Poeciliidae) are believed by some writers to be related to trout-perches (Percopsiformes) and by others to silversides, flying fishes, and their relatives (Atheriniformes). Thus, future study may result in the transfer of some groups from the Paracanthopterygii to the Acanthopterygii and vice versa.

(G.J.N.)

Flying fishes, needlefishes, cyprinodonts, and allies (Atheriniformes)

The order Atheriniformes contains 15 families of marine and freshwater spiny-finned fishes, including the flying fishes, needlefishes, silversides, and cyprinodonts. The last group, the Cyprinodontidae, is an abundant tropical and subtropical family that includes the guppies, mollies, swordtails, and many other aquarium fishes. In addition to the Atheriniformes, this section will treat the three smaller related orders Beryciformes, Zeiformes, and Lampridiformes, the most primitive groups of the superorder Acanthopterygii or spiny-finned fishes.

GENERAL FEATURES

Beryciforms and zeiforms are mostly deep-bodied fishes of small to moderate size, a foot or less in length. The lampridiforms include a few rare, deep-bodied forms, notably the disk-shaped opah, which may reach more than 136 kilograms (300 pounds) in weight, but the majority are much elongated, ribbonlike fishes, including the giant oarfish, *Regalecus,* which reaches eight metres (25 feet) in length and is the probable source of many sea-serpent legends. The atheriniform silversides, flying fishes, needlefishes, and halfbeaks tend to be slender, elongate fishes, up to 0.3 to 0.9 metre (two to three feet) in length. The cyprinodonts and their relatives are diminutive and include some of the smallest vertebrates. Many cyprinodonts are important as experimental animals in biological research and as useful predators in the control of insect-borne diseases.

NATURAL HISTORY

Most beryciforms, zeiforms, and lampridiforms are inhabitants of the open oceans, usually living at considerable depth, and little is known of their natural history. All appear to produce numerous small eggs. The best known of the beryciform groups are the squirrelfishes and soldierfishes (family Holocentridae), abundant around coral reefs in warm seas. Typical of beryciforms, they are red in colour, with large eyes. Holocentrids are nocturnal,

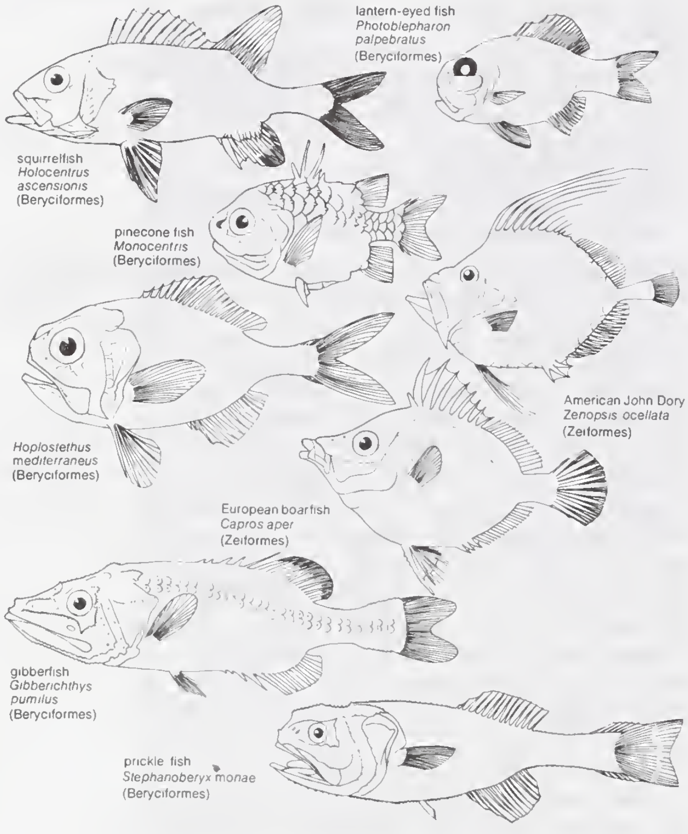

Figure 29: Body plans of Beryciformes and Zeiformes.

From (*Hoplostethus, Stephanoberyx*) *The Fishes of North and Middle America* by David Starr Jordan and Barton Warren Evermann, Bulletin of the U S National Museum No 47, 1900, reprinted by permission of the Smithsonian Institution, (*Gibberichthys*) A E Parr, *Bingham Oceanographic Collections*, vol 14, no 6, (*Photoblepharon, Monocentris*) P P Grasse, *Traite de Zoologie*, vol 13 (1958), Masson et Cie, Editeurs, (*Capros, Holocentrus, Zenopsis*) N B Marshall, *The Life of Fishes* (1965), Weidenfeld & Nicolson, Ltd

Luminescent organs

sheltering in crevices during the day and emerging at night to feed. They are notable sound producers, having special drumming muscles attached to the swim bladder, and many have connections between the swim bladder and the ear to improve hearing: presumably these sounds and their reception play some part in courtship. In holocentrids the young (larva) is quite unlike the adult, with a projecting spiny snout and enlarged spines in front of the gill cover. There is a pronounced metamorphosis (a major change in body plan on reaching maturity). It is probable that some of the deep-sea beryciforms undergo similar metamorphoses; the larva of the fanged *Caulolepis* was for many years placed in a different family from the adult, and the genus *Kasidoron*, recently discovered and placed in a distinct family, may be only the larva of *Gibberichthys*. Another family of beryciforms found near the surface is the Anomalopidae, or "strange-eyes," so-called because of a large luminous organ lying directly below the eye, which is switched on by muscular eversion, turning the inside outward (in *Anomalops*) or by the withdrawal of a pigmented cover (in *Photoblepharon*). The Monocentridae, the bizarre pinecone fishes, are another beryciform group with luminous organs, in this case located on the chin. The majority of beryciforms are generalized predators, but a few coral-reef forms are grazers.

Among zeiforms, at least one species, *Zeus faber*, produces sounds by drumming muscles and breeds inshore. Little is known of the biology of the oceanic forms, but some certainly undergo metamorphosis, especially the Oreosomatidae, whose larvae are studded with large, spinous tubercles. All zeiforms are highly compressed fishes, with stiff bodies and long dorsal and anal fins: probably they swim by undulating these fins rather than by flexing the body. This slow, stealthy mode of swimming, coupled with their highly protrusile mouths, adapts them for stalking and engulfing prey.

The lampridiforms are all oceanic fishes. Metamorphosis is recorded in dealfishes and oarfishes, the young of which have rather deep bodies and greatly elongated finrays. All are slow swimmers, and the larger forms, the opah and the oarfishes, which are characteristic of surface waters, use their protrusile, toothless mouths as traps for small, planktonic (free-floating) organisms. The deep-sea forms have feebly toothed jaws and are predators. A remarkable modification in one lampridiform, *Lophotes*, is the presence of an ink sac, discharging a viscous, black secretion into the hindgut, thence into the water. These fishes probably use their ink as a defense mechanism, as do squids. *Stylephorus*, a highly modified deep-sea lampridiform, has projecting, telescopic eyes.

Flying fishes

Among atheriniforms there is an extraordinary variety of locomotor, reproductive, and ecological adaptations. Locomotor modifications are most marked in the flying fishes, but the origin of the "flying" habit can be traced in flying fish relatives such as the halfbeaks, garfishes, and skippers. All are surface fishes of the open ocean and are capable of leaping or skipping on the surface, sometimes for considerable distances, thus allowing them to escape predators. The tail (caudal) fin is usually asymmetrical, with the lower lobe longer than the upper, and while the body is out of the water the lower lobe vibrates as a scull driving the fish along. True flying fishes have a similar asymmetrical tail, but the pectoral fins are inserted high on the shoulders and are greatly enlarged, with long, stiff fin rays supporting a web of skin. In the most highly evolved flying fishes, the pelvic fins are also enlarged and winglike. The fish accelerates under water by rapid vibration of the tail and fin, with the paired fins furled. On breaking surface, the pectoral fins are expanded, but the lower lobe of the tail remains in the water, sculling rapidly and accelerating the fish. The pelvic fins are then expanded, lifting the tail out of the water and initiating gliding flight. As airspeed is lost, the fish may fall back into the sea or furl its pelvic fins, dropping the lower lobe of the tail into the water and picking up speed for a further glide. Up to five repeated takeoffs have been observed, producing a total flight time of almost half a minute and covering several hundred yards.

Marine atheriniforms are mostly predators, the predatory habit being most highly developed in the garfishes and needlefishes, with their long, formidably toothed jaws. Freshwater atheriniforms are generally adapted for feeding at the surface, on insect larvae and small crustaceans.

All atheriniforms are characterized by the production of few, large, adhesive eggs, by mating in pairs, usually accompanied by sexual dimorphism (*i.e.*, the sexes markedly different), and many groups exhibit various reproductive specializations, the most advanced of which is viviparity (the production of functional young, instead of eggs). The young are normally miniatures of the adult and there is no metamorphosis. Sauries, needlefishes, flying fishes, and marine halfbeaks are pelagic (*i.e.*, inhabiting open ocean) and breed either in the open sea (sauries, flying fishes) or near the shore (needlefishes, halfbeaks), the eggs often attaching to floating objects by adhesive filaments. The freshwater halfbeaks are mostly viviparous and have an elaborate courtship behaviour.

Atheriniforms of the suborder Atherinoidei fall into two groups, the silversides (Atherinidae and their close relatives) and the more specialized phallostethoids. The silversides are mainly freshwater fishes and show some reproductive specializations in courtship behaviour and sexual dimorphism (coloration and fin shape). They breed near the shore, attaching the eggs to plants. The grunion (*Leuresthes tenuis*) breeds on the California coast, schooling in the surf at extreme spring high water and spawning on the shore, where the female buries the eggs in the sand. The eggs hatch when they are exposed by the next spring tide, two weeks later. In phallostethoids, males have a fleshy, asymmetrical intromittent organ, the priapium, under the throat, formed from the modified pelvic fins. Although fertilization is internal, viviparity is not known to occur.

Breeding specializations of cyprinodonts

Even the most primitive atheriniforms in the suborder Cyprinodontoidei show the usual reproductive specializations of the group: sexual dimorphism and complex behaviour patterns in courtship and spawning. In the Mexican topminnows (Goodeidae) viviparity has developed, the embryos absorbing nourishment within the oviduct of the mother by means of threadlike outgrowths. In the livebearers (Poeciliidae), an abundant group in the American tropics and subtropics, sexual dimorphism affects many parts of the body. Males have a complex intromittent organ, the gonopodium, formed of modified anal fin rays. One member of the group is oviparous, shedding the eggs while the embryo is only partially developed, but in the guppies, mollies, and swordtails, where the male is much smaller than the female and more brightly coloured, the young are born fully developed, and a series of broods, at about monthly intervals, may result from a single fertilization. In wild cyprinodont populations the sex ratio is frequently unusual, with many females to each male. In *Jenynsia* and *Anableps* (the four-eyed fish) the gonopodium and female reproductive opening are asymmetrical. Both dextral and sinistral forms occur within a species, dextral males mating with sinistral females and vice versa.

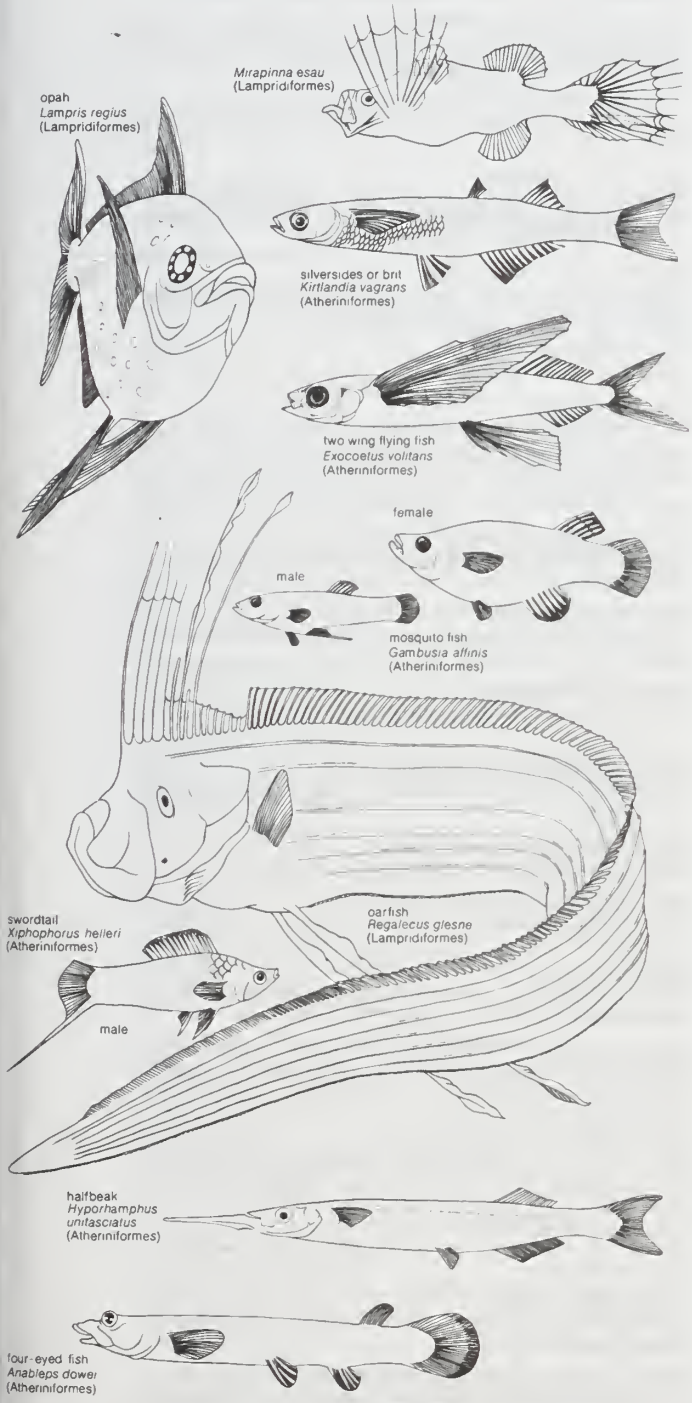

Figure 30: Body plans of Lampridiformes and Atheriniformes.

Ecological adaptations in atheriniforms are most marked in freshwater species. Cyprinodonts are among the hardiest of fishes and survive in the most rigorous environments. Some cyprinodonts have become adapted to life in hot springs in Africa and America and seem capable of surviving water temperatures approaching the coagulation point of protoplasm. Others survive in stagnant, almost or completely deoxygenated waters, either by taking in water at the surface film, or by breaking surface and gulping air, although no accessory respiratory structures are developed. Some cyprinodonts have overcome the rigours of a seasonal tropical habitat by becoming annuals, growing rapidly and reaching sexual maturity in small temporary bodies of water during the wet season, and on the approach of the dry season, mating and burying the eggs in the mud. The eggs can survive droughts for up to five years, hatching rapidly with the onset of the succeeding wet season. Perhaps another response to rigorous environments is the occurrence in some cyprinodont populations of functional hermaphrodites, capable of self-fertilization and hence of maintaining a population from one surviving parent.

FORM AND FUNCTION

The fishes discussed here share a number of anatomical features typical of the more advanced teleosts. These include a closed swim bladder; separation of the parietal bones by the supraoccipital; jaws that protrude to some extent, with the maxillary bone (toothless except in a few beryciforms) acting as a lever to move the large premaxilla; the pectoral fins inserted high on the flank and the pectoral girdle without a mesocoracoid arch; and a tail skeleton supported by two or less vertebrae. Otherwise, there is considerable structural variation.

Structure of beryciforms
